PREFACE

The Department of the Interior has a basic responsibility for the appraisal, conservation, and efficient utilization of the Nation's natural resources, including water as a resource, as well as water involved in the use and development of other resources. As one of the several Interior agencies, the U.S. Geological Survey's primary function in relation to water is to assess its availability and utility as a national resource for all uses. The U.S. Geological Survey's responsibility for water appraisal includes not only assessments of the location, quantity, and availability of water but also determinations of water quality. Inherent in this responsibility is the need for extensive water-quality studies related to the physical, chemical, and biological adequacy of natural and developed surface- and ground-water supplies. Included, also, is the need for supporting research to increase the effectiveness of these studies.

As part of its mission the Geological Survey is responsible for a large part of water-quality data for rivers, lakes, and ground water that is used by planners, developers, water-quality managers, and pollution-control agencies. A high degree of reliability and standardization of these data is paramount.

The series of manuals on techniques describes procedures for planning and executing specialized work in water-resources investigations. The material is grouped under major subject headings called books and is further subdivided into sections and chapters. Book 1 is on the collection of water data by direct measurement. Section D is on water quality.

The unit of publication, the chapter, is limited to a narrow field of subject matter. This format permits flexibility in revision and publication as the need arises. "Guidelines for Collection and Field Analysis of Ground-water Samples for Selected Unstable Constituents" is the second chapter to be published under Section D of Book 1. The chapter number includes the letter of the section.

GUIDELINES FOR COLLECTION AND FIELD ANALYSIS OF GROUND-WATER SAMPLES FOR SELECTED UNSTABLE CONSTITUENTS

By Warren W. Wood

Abstract

The unstable nature of many chemical and physical constituents in ground water requires special collection procedures and field analysis immediately after collection. This report describes the techniques and equipment commonly used in the collection and field analysis of samples for pH, temperature, carbonate, bicarbonate, specific conductance, Eh, and dissolved oxygen.

Introduction

Samples of ground water are obtained and analyzed to evaluate the chemical and physical quality of the water and to aid in understanding the geochemical and hydrologic relationships in an aquifer. These objectives require that the water sample represent the geochemical environment as accurately as possible.

Some properties or constituents in ground water may change dramatically within a few minutes or hours after sample collection. Immediate analysis in the field is required if dependable results for these parameters are to be obtained. Samples for other constituents may be stabilized by preservative treatment. Some examples of preservative treatment are refrigeration or the addition of toxic metals such as mercury to minimize chemical changes due to biologic activity and the addition of acid to prevent the precipitation of metal ions.

This manual is designed to provide guidelines for the collection and field analysis of common unstable constituents or properties of relatively shallow ground water and is intended to be a supplement to the manual on "Methods for Collection and Analysis of Water Samples for Dissolved Minerals and Gases" (Brown and others, 1970). Techniques for sampling and analyses for unusual or uncommon constituents as well as deep ground waters have been omitted from this report. The reader is referred to Presser and Barnes (1974) for techniques on collection and field analysis of ammonia and hydrogen sulfide gas.

The techniques and equipment described in this manual are derived from many workers including William Back, Ivan Barnes, H. C. Claasen, Bruce B. Hanshaw, Gerth E. Hendrickson, John D. Hem, Blair Jones, Donald Langmuir, F. J. Pearson, Jr., Jack Rawson, and Isaac Winograd. My sincere thanks goes to these and other workers from whom I have acquired information included in this manual.

The recent development of sophisticated portable field equipment has permitted a very accurate and precise analysis of water for some unstable constituents or properties at the collection site; however, all methods described in this manual are subject to revision as improved techniques and equipment are developed or become available.

The English units used in this report may be converted to metric units by the following factors:

From	*Multiply by*	*To obtain*
feet	0.3048	metres
gallons	3.785	litres
gallons per minute	.06309	litres per second
inches	25.4	millimetres
	2.54	centimetres
ounces	28.349	grams

General criteria for sampling of ground water for geochemical studies

A working hypothesis on geochemical controls affecting the water in an aquifer is essential before collection of water samples is begun. All water analyses for the area of study, including those that are available from city, county, state, and Federal agencies, should be evaluated prior to the development of a sampling program, even though the accuracy of these analyses may be inadequate for the purposes of a particular study. Surface-water analyses, particularly of samples collected under base-flow conditions, should not be overlooked in evaluating existing chemical and physical data. Additional information on geochemical conditions can often be obtained by the extrapolation of data from known areas or regions of similar hydrologic, geologic, and climatic environments.

The working hypothesis on the chemical controls affecting the water quality of an aquifer, as developed from existing data, will aid in selecting the sites for the collection of samples; identifying the number and types of field or laboratory analyses required; and determining the methods for sample collection, treatment, and preservation. This information is required so that the applicable equipment, instruments, containers, and preservatives can be obtained and the sampling and analytical schedules can be organized.

Method of sample collection

Springs

Excellent samples for the determination of some water-quality constituents can be obtained from springs if suitable sampling precautions are taken. Small springs in unconsolidated deposits can be sampled by driving a well point or slotted pipe to a depth of 1 metre or less into the ground adjacent to the spring. The water will often flow from this type of installation. If it does not flow, a small "pitcher pump" can be used to collect the sample. Attempts to collect samples from small springs and seeps, without the use of pipes, result in almost certain contamination of the sample by soil bacteria, particulate matter, and atmospheric oxygen. It is often difficult, even when using a driven pipe, to collect a sample that does not contain dissolved oxygen. If the water contains easily oxidized metals such as iron and manganese, the dissolved-oxygen contamination may preclude the use of a small spring or seep as a satisfactory site for the collection of samples for the determination of these metals and other properties or constituents such as pH and oxidation-reduction potential. If the sample is to be used for the determination of trace metals, it is necessary to use plastic pipe and well screen that has been thoroughly cleaned, rather than iron pipe.

Large springs in consolidated rock usually are better sampling points than other types of springs. However, obtaining a representative sample of vigorously upswelling water at the orifice of a large spring may be difficult and may require a boat manned by several people. Even if the spring depression is narrow and can be waded, collection of a representative sample by forcing a bottle held by hand or attached to a rod down into the upswelling water is difficult. In either case, where the sample is collected directly in the bottle, the sample is always contaminated with oxygen.

Although thief-type samplers (fig. 1) can be used to collect unoxygenated samples, they are usually difficult to emplace in a "boiling spring." An additional problem with the use of thief samplers is that the closing messenger may not function properly in upswelling waters. Both nonmetallic and brass thief samplers are available. The nonmetallic type should be used for the collection of samples to be analyzed for trace metals.

A heavy metal pipe pushed into the mouth of a spring can be used to provide a steady flow from which the sample can be collected. Although this sampling system minimizes the potential for atmospheric contamination, experience has shown that dissolved oxygen is inevitably present in samples collected in this manner. The samples collected by use of the metal pipe may not be suitable for the analysis of trace metals or other properties affected by dissolved oxygen.

An inexpensive ($20–$30) submersible-elec-

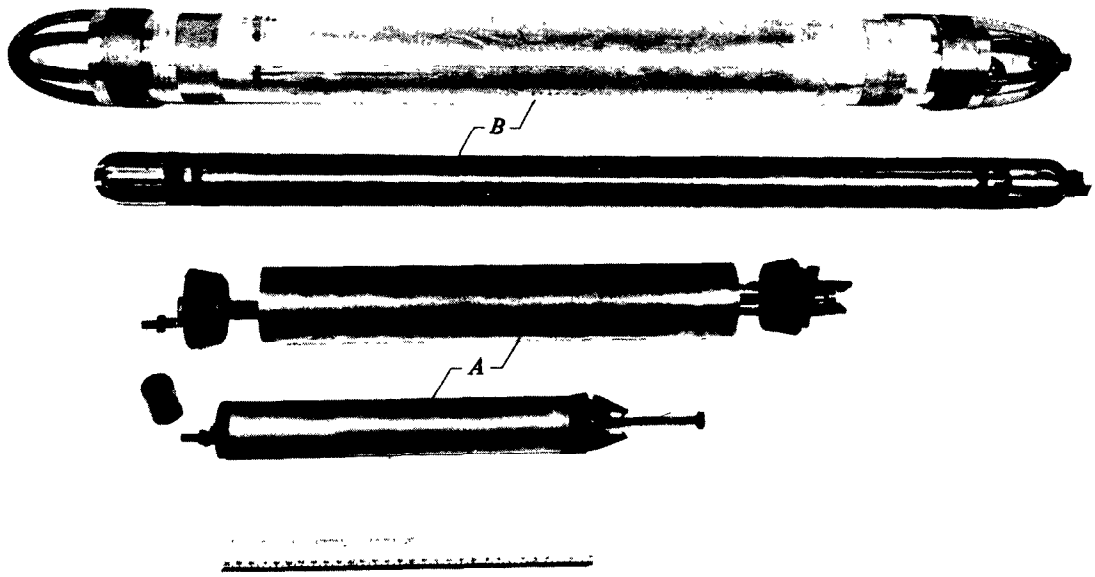

Figure 1 —Thief-type samplers. A, Foerst. B, Ball-valve

tric pump of the type sold at garden-supply stores and used for home water fountains can be a very effective sampler. These pumps, which have plastic housing, impellers, and tubing, can be used to collect samples for trace metals as well as major constituents. A suggested procedure is to secure the pump to a pole or pipe and push it into the mouth of a spring. With the delivery tube running to the shore, the pump is started and the sample collected. These pumps will deliver 10–20 litres per minute and greatly simplify the process of sampling from springs.

The main disadvantage of this pump system is that it requires an independent power supply. However, these pumps have a low power requirement, usually less than 2 amps, and can be used with a 12-volt automobile battery fitted with an inexpensive ($10–$20) inverter. The inverter, which converts 12-volt direct current to 110-volt alternating current, is connected to the battery, and the pump is plugged into the inverter. Because the cord supplied with these pumps usually is too short for most sampling, a waterproof connector and extension cord must be added. A portable gasoline-powered generator will also provide a satisfactory power supply, but it is usually more awkward to use than the automobile battery and inverter arrangement.

In spite of the limitations and sampling difficulties, sample collection from springs can be useful for many constituents if the limitations are recognized and considered prior to sampling.

Wells

The depth of the pump in a well and the water level during pumping should be known before samples are obtained. If the water level is at or near the pump intake, atmospheric oxygen may be entrained in the discharge and easily oxidized metals such as iron may precipitate prior to sampling. If water-level and pump depth information is not available, the discharge should be checked for dissolved oxygen before samples are collected. If ground water in the region being studied normally contains no oxygen, the presence of oxygen indicates contamination by the pumping process. However, in ground-water systems that contain little oxidizable material, dissolved oxygen may exist naturally. The presence of naturally dissolved oxygen may be verified by sampling other wells in the aquifer.

Multiple-screen or open-hole wells that receive water from several aquifers should be avoided in sampling for geochemical studies. Pumping from between well packers can sometimes be used to obtain samples from a particu-

lar aquifer in multiple-aquifer wells if the sample information justifies the cost involved. A driller's log that gives the construction details of the well as well as a lithologic description of the units penetrated is essential.

If any uncertainty exists as to depth of the producing aquifer or depth of the well, the total depth of the well should be measured and a flowmeter survey conducted to determine the source of the water prior to sampling. Difference in temperature of water compared to other wells in the area may represent different production depths. A flowmeter survey can also be useful in determining if multiple-aquifer flow exists in the system and can offer an explanation for chemical quality anomalies that are often observed within an apparent single-aquifer system.

To obtain a representative sample from an aquifer at a given location, a well must be pumped until the temperature, pH, and specific conductance are constant. This is the minimum required precaution for insuring that a sample adequately represents the water in the aquifer. pH is usually the last parameter to obtain a reproducible reading and, consequently, is the most sensitive test for many wells. There is no specific volume of water that constitutes a minimum pumping time. Municipal, irrigation, and industrial wells that are in nearly constant use require only a few minutes of pumping before stable conditions are observed and samples can be collected with confidence.

Standby, observation, new, and little-used wells may require a day or more of pumping before the water is of constant quality. A log of specific conductance, pH, and temperature for water pumped from these seldom used wells should be kept until these parameters stabilize. Measurement of drawdown during this stabilization period is often helpful because changes in the proportions of discharge coming from different producing zones may be reflected by new pumping levels.

The most representative water samples usually can be obtained from municipal, industrial, or irrigation wells. Because of their constant pumping and high yield, these wells draw water from a large area of the aquifer and usually insure a representative sample. In addition, other hydrologic data are usually available at these sites. Available data on approximate discharge and duration of pumping prior to sampling should be recorded for any of these wells.

Potential contamination, precipitation of solutes, and loss of dissolved gases can be minimized by collecting the sample as close to the wellhead as possible. Many domestic and other types of wells are poorly designed for sampling. The plumbing is often inaccessible, and samples can be obtained only after water has gone through a pressure tank, water softener, or iron filter. Analysis of water from these wells are of little value in geochemical studies.

Wells that do not have a suitable sampling point often can be modified so that a representative sample can be collected. However, before any modifications are performed, permission of the well owner should be obtained. Any field kit used for such modifications should include a battery-powered electric drill and bits and taps for ⅛-inch and ¼-inch pipe thread. In addition, plugs, petcocks, plastic tubing, and wrenches for these pipe sizes should be included in a field kit. (See table 1 for a suggested list.) Adaptors, reducers, couplings, and nipples of all standard sizes and material are essential for utilizing existing sampling taps. Many sampling taps on industrial and municipal wells have either a garden-hose fitting or a smooth-surface faucet that requires a special adaptor.

Often the only wells for which complete hydrologic data are available are small-diameter observation wells that are not equipped with a pump. If the diameter of the well is sufficiently large, a submersible pump can be used to obtain samples. If the water level is less than 7 metres below the surface, a pitcher pump may be used for sample collecting. In using this method, however, it is difficult to prevent oxygenation.

For small-diameter wells, a hand-operated thief sampler can be used to collect samples from any depth in the wells. The quality of the water standing in an unused well generally does not reflect the quality of the water in the aquifer. Before sampling with a thief sampler, the well should be bailed until the specific con-

Table 1 —Supplies and equipment included in a field kit suitable for water sampling from a well

Two each square-head male pipe-thread plugs, ⅛, ¼, ½, and ¾ inch.
Two each reducer bushings, ¾ to ½, ½ to ¼, and ¼ to ⅛ inch, male pipe thread to female pipe thread
Two each reducer couplings, 1 to ¾, ¾ to ½, ½ to ¼, and ¼ to ⅛-inch pipe thread
Two each long nipples, male pipe thread, 1, ¾, ½, ¼, and ⅛ inch.
One each tees, ¾ and ½ inch.
One each elbows, ¾ and ½ inch.
15–50 feet of ⅜-inch plastic tubing.
15–50 feet of ¼-inch plastic tubing.
15–50 feet of ½-inch plastic garden hose with fittings.
Two each male connectors garden hose to pipe filtering.
1–6 feet of soft rubber hose, ¼-inch ID, and ⅜-inch ID.
Three each male connectors, ¼-inch tube to ⅛-inch pipe thread
⅜-inch tube to ⅛-inch pipe thread
⅜-inch tube to ¼-inch pipe thread
¼-inch tube to ¼-inch pipe thread
Two each tubing union tees, ¼ and ½-inch tubing.
Two each tubing unions, ¼ and ⅜ inch.
Two each male branch tees, ¼ and ⅜ inch.
Two each low pressure needle valves, ¼ and ⅜-inch tubing.
A tool box containing two pipe wrenches and two crescent wrenches as well as screwdriver, pliers, hacksaw, and so forth.
Several shutoff and control valves of the common tube and pipe sizes are desirable.

ductance, pH, and temperature of the water are constant. Collection of a sample by bailing and filtering a sample from a thief sampler without introducing dissolved oxygen is nearly impossible.

For some wells, it may be advantageous to use a motor-operated small-diameter unit controlled by an uphole power source and switch. Motorized units are of course more expensive than hand operated ones, and the operation is more involved because a truck with a power winch must be used to raise and lower the unit. Again, the well should be bailed until the values of pH, temperature, and specific conductance are constant.

A small-diameter hand-operated bailer may also be used to collect samples from wells. Figure 2 shows such a homemade bailer that can be made in about an hour at a cost of a few dollars. Copper tubing, stainless steel, or PVC

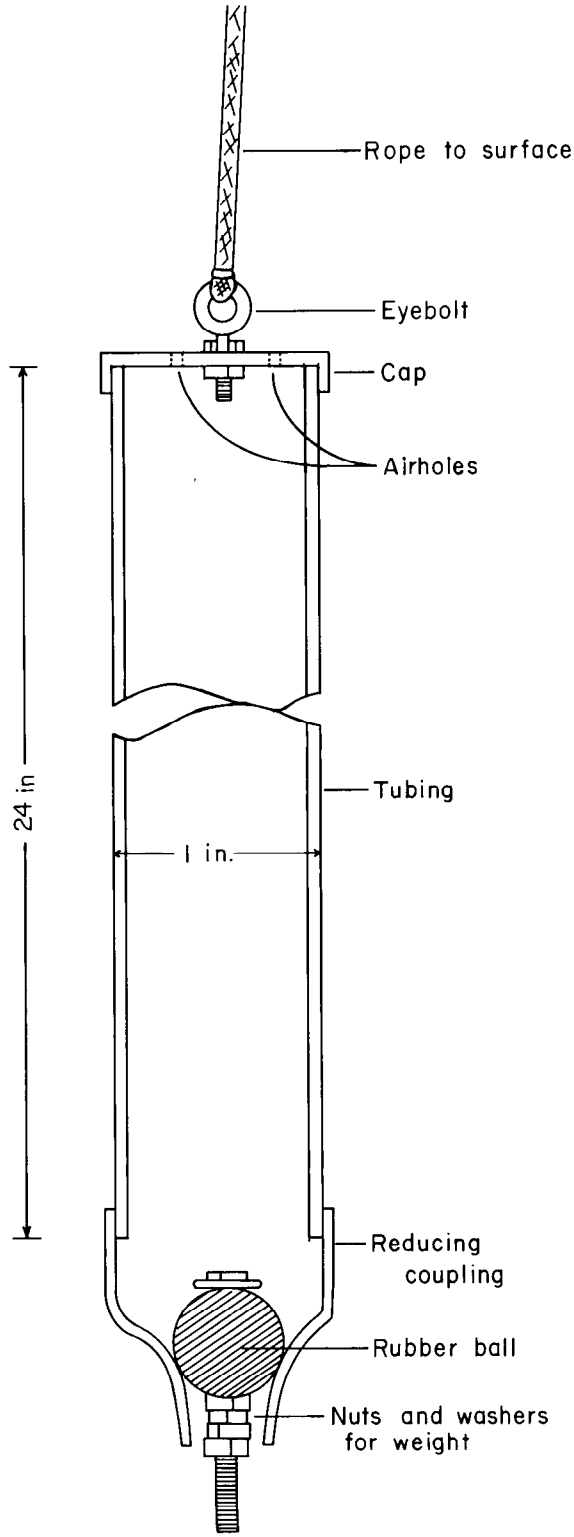

Figure 2 --"Homemade" bailer for collecting water samples from small-diameter wells

Figure 2 - "Homemade" bailer for collecting water samples from small-diameter wells

(polyvinyl chloride) plastic can be used; if plastic is used, a weight must be attached to the unit so that it will submerge. Plastic and stainless-steel construction is preferable if analyses are to be made for trace metals. The sample is contaminated with oxygen in this system, and particulate matter is often collected if the bailer strikes the bottom of the well. With any bailer or thief-type sampler, there is always the danger that the sample is a mixture of stagnant water in the well bore and water from the aquifer. Even the precaution of checking the sample for constancy of pH, temperature, and specific conductance may not give complete assurance of a representative sample.

A problem of fluid quantity exists with any of the bailer or thief-type methods of collection because an inordinate amount of time may be required to make 50 or 100 trips with a sampler to insure that the stagnant water in a well has been removed. Airlift pumping is an effective method of developing small-diameter wells but is generally a poor method of collecting a sample for chemical analysis. The air used for pumping obviously contaminates the sample, but perhaps more importantly, the turbulance with which the water is brought to the surface may have significant effects on pH, carbonate, bicarbonate, and temperature.

A useful combination of sampling techniques in small-diameter wells is to use the air pump to remove water until chemical conditions are stable and then to make several trips with a thief sampler or bailer to collect the sample. With all bailer or thief methods, it is extremely difficult to avoid oxidizing iron or manganese when filtering. For this reason, analyses for these elements should not be made if the bailer sample contains particulate matter that requires filtering.

Unfortunately, there are no well-defined criteria that apply to all methods of sampling for trace metals. The only general rule is to avoid contact with any metals in the collection system. Because this rule is often in conflict with the practical problems of collecting the sample, some compromise is usually necessary, and each sampling situation must be evaluated individually.

Unsaturated zone

Water sampling beneath a waste-disposal pond, feedlot, sanitary landfill, recharge pond, or any other system in which there is unsaturated flow requires special techniques. One method that has been used consists of a buried porous-ceramic cup (suction-lysimeter) with two lines to the surface, by which vacuum and pressure are applied, and from which the sample is collected. The construction details of this device are shown in figure 3. Additional details are given by Wood (1973).

In general, the system is operated by applying a vacuum greater than soil-moisture tension to a buried porous cup and thereby inducing the water to flow into the cup. To withdraw the sample, an increased vacuum is applied which causes water to flow past the check valve into the vacuum line. Gas pressure (inert gas) is then applied to one tube of the two-tube sys-

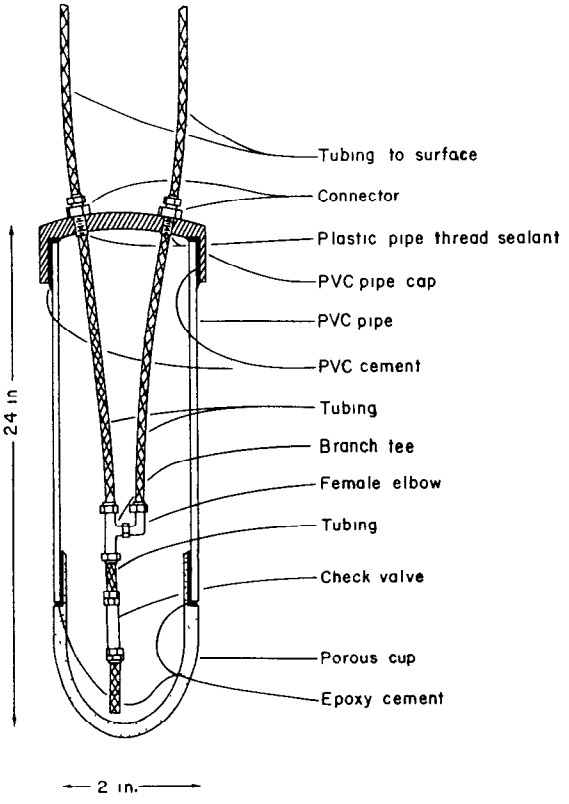

Figure 3.—Porous-cup assembly used for sampling in the unsaturated zone.

tem to force the sample to the surface. A check valve in the cup assembly prevents pressurization of the porous cup and backflow of the sample. This system has been used successfully in fine sand where there has been significant amount of flow; whether it will give satisfactory results in all unsaturated flow requirements has not yet been ascertained.

Sample filtration and acidification

Water that appears to be clear may contain considerable amounts of particulate matter in suspension. This is particularly true of water from new or little-used wells, such as those used for water-level observations or standby municipal and industrial supplies. The quantity of sediment discharged from a well is affected by the type of pump, construction of the well, screen size, type of screen, the pumping rate, and drawdown as well as the chemical stability of the system. The particulate matter in a water sample must be removed prior to most analyses, particularly if the sample is to be acidified, because the addition of acid will cause much of the particulate matter to dissolve. For example, the acid used for bicarbonate titration will dissolve particulate calcium carbonate, resulting in an analysis that shows an anomalously high bicarbonate content. The addition of acid prior to filtering may also result in exchange of hydrogen ions from the acid with cations from the particulate matter, thereby increasing the cation concentration of the water.

The wrong filtering technique will do as much damage to the accuracy of some analyses as will no filtering at all. Samples used for temperature measurements, dissolved oxygen, Eh, and pH should not be filtered. Vacuum filtering exposes the sample to the atmosphere and may also remove dissolved carbon dioxide from the water. The removal of carbon dioxide may significantly change the concentration of bicarbonate, carbonate, and influence the pH. Ground-water samples for the determination of these and other properties or constituents affected by the loss of carbon dioxide or contamination by oxygen should not be vacuum filtered.

A simple modification of the Skougstad-type plastic filter (Brown and others, 1970), commonly used by the U.S. Geological Survey, permits exclusion of the atmosphere during filtering. The top of the unit may be modified to include an inlet-delivery tube that extends to within a fraction of an inch of the bottom of the inside of the filter. The old pressure inlet is used as the new outlet, and control valves are placed on the inlet and the outlet tubes (fig. 4). This modification permits incoming water from a sampling line connected to the well discharge to fill the filter from the bottom, expelling air and overflow sample through the exit line. Discharge to the filter unit is controlled by the valve on the intake.

Before beginning filtration, the filter unit should be completely disassembled and thoroughly washed with the water to be sampled. Take special care to install a new styrofoam filter-support pad or insure that there are no stains or particulate matter on the old pad. A new membrane filter of the proper diameter (102 mm) and pore size (0.45 μm) is fitted to the filter unit, and the top and bottom are securely fastened.

Water introduced into the filter will immediately begin to drip from the discharge tube, and this water can be used to rinse pipets, sample bottles, and other equipment. Once the filter unit is full and all air is expelled, water is permitted to continue flowing through the

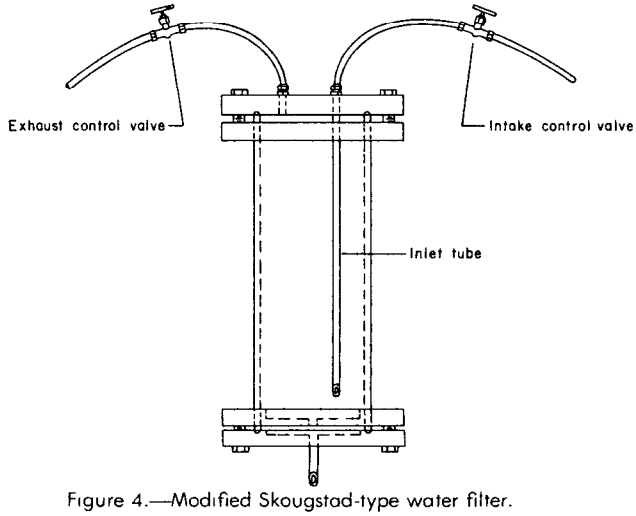

Figure 4.—Modified Skougstad-type water filter.

filter and out the exit tube until three or four filter volumes have flushed through the unit. This procedure makes certain that water that has been in contact with the atmosphere and any soluble impurities in the unit are removed.

The valve on the exit tube is closed, and the pressure from the well is used to filter the water. Pressure is controlled by the valve on the inlet tube and should be adjusted so that it is only sufficient to create a gentle flow from the discharge tube. A large pressure drop across the filter should be avoided to minimize the loss of dissolved gases from the sample. A sample bottle that has been thoroughly rinsed several times with the sample filtrate is placed under the filter for collection of the sample.

If water pressure is insufficient for filtering, an inert gas such as nitrogen or argon can be used to force the sample through the filter. To utilize gas pressure for filtration, the filter unit is filled with water as above, and the gas source is attached to the exit tube, the inlet tube is closed, the pressure is applied,and the sample collected from the discharge tube. Compressed air or carbon dioxide should not be used because these gases will influence the composition of the sample.

The 0.45-micrometre porosity filter has been widely adopted for separation of suspended matter from water samples. It represents a compromise between complete removal of the particulate material and speed with which filtration may be completed. Colloidal material with particles less than 0.45 micrometre in diameter is generally present in surface water and may occur in some ground water. Such material can pass through the filter and may strongly influence analytical values for iron and manganese (Kennedy and others, 1974). The problem may be partly alleviated by using 0.10-micrometre porosity filters (Kennedy and others, 1974).

The filtering process produces a "filter cake" of particulate material that decreases the particle size that can pass through the filter. Building of a filter cake may destroy the comparative uniformity of trace metals in successive aliquots. There is no apparent solution to this dilemma, but careful notation of the volume of water filtered and the amount of suspended material in the sample may be useful in evaluating analytical results.

The use of 0.1-micrometre filter membrane may reduce variance of trace metals between aliquots. The use of this filter membrane, however, requires considerably more filtration time because of rapid plugging from suspended solids in the sample. The 0.1-micrometre membrane filter should be used only in special situations that have been discussed with the district water-quality specialist or with personnel of the Central Laboratory System.

Porosity of the filter used should be recorded with the analytical data. Chemical analysis of particulate material retained by the filter may be important for some studies. To use this information the total volume of water filtered must be known.

If the filtered samples are to be acidified, double-distilled reagent-grade nitric acid should be added to the sample bottles after a few millilitres of the sample have been collected, to minimize oxidation, precipitation, and adsorption. Acid is more effective in preventing precipitation than in removing the precipitated minerals from the walls of the sample bottles. Sufficient acid must be added so that the resultant pH is 3.0 or less; usually 1 millilitre of acid to 1 litre of sample is sufficient. Convenient containers for transporting ultra high purity acid in the field are 2-ounce polyethylene or Teflon dropping bottles (fig. 5). Disposable glass ampoules of acid obtained from the Central Laboratory are even more convenient to use than the dropping bottles, and the chance of contamination is less with the ampoules. The ampoules can be carried in the field in their styrofoam shipping case with little danger of breakage.

Sampling for trace metals analysis

Some of the preceding sections have shown that the collection of water samples for trace metals analysis without contamination by atmosphereic oxygen is difficult. Contamination of samples with the trace metals themselves also may present a serious problem because of the widespread use of metallic casing, screen,

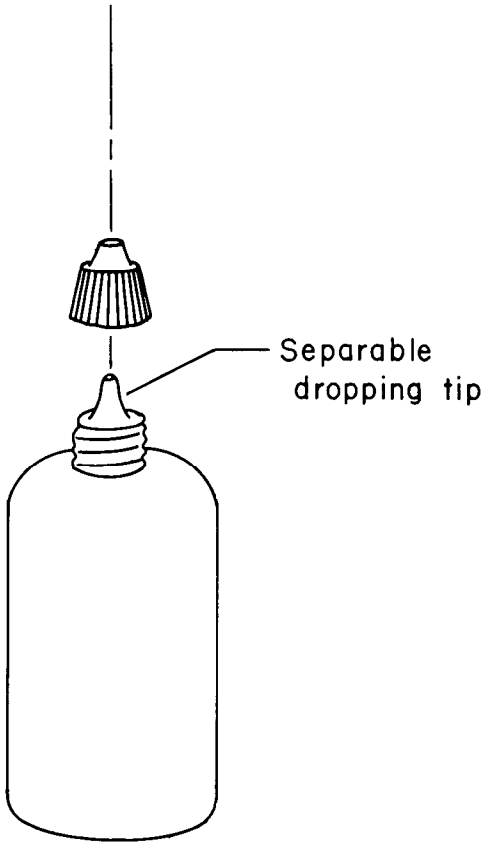

Figure 5 —Acid bottle used for field sampling

and pump columns for well construction. One solution to this potential contamination problem is the installation of a nonmetallic well and screen equipped with a nonmetallic pump or sampling device. This procedure is extremely expensive for an areal survey and is seldom practiced. Another solution to this problem is to confine the sampling to springs which are not in contact with metallic objects.

Because of the lack of definable springs in many aquifers and the near nonexistence of nonmetallic well construction, some compromise on the collection of samples for trace metals analysis is necessary. The usual compromise is to sample from a high capacity well which has been installed and operating for several years. The rationale of this choice is based upon the short time of contact of the water with the well structure (often less than 30 seconds). Except under unusual circumstances, the short contact should preclude contamination of the sample with trace metals. If samples from wells with metal construction are collected for trace metals analysis, this should be clearly stated with the published data.

Field-analysis procedures

Specific conductance

The specific conductance of a water sample is a measure of its ability to carry an electrical current under specific conditions. Specific conductance, which is a measure of the ionized salts, gives an indication of the concentration of dissolved solids in the water.

There are several reasons for determining the specific conductance of a sample in the field at the time of collection rather than waiting for a laboratory measurement. The field determination can be used as an aid in evaluating whether a sample is representative of water in the aquifer. For example, in new or little used wells, or in wells that have been recently drilled, grouted, or cemented, chemical changes in the pumped water may be rather large, and the well may require prolonged pumping to insure that the sample is representative of water in the aquifer. Specific-conductance determinations can be used to indicate that sufficient water has been pumped and that the quality of the water is stabilized.

A specific-conductance value that is markedly different from values obtained in nearby wells may indicate a different source of water, such as induced recharge, contamination from the surface, or leakage from a formation that contains water of different quality. Detection of an anomaly may indicate that more detailed sampling or reevaluation of the well is required. If so, the work can usually be done more economically at the time the original sample is collected rather than several weeks or months later.

The specific conductance of a sample can change with time owing to the precipitation of minerals from the water once the sample is in the environment of the container. A sample that has been acidified or otherwise treated will not yield an accurate representation of the specific conductance of the water in the

aquifer; therefore, it is essential to obtain an accurate field determination.

Summary of the method

The ability of a solution to conduct an electrical current is a function of the concentration and charge of the ions in solution and of the rate at which the ions can move under the influence of an electrical potential. As the number of ions per unit volume of solution increases, the rate at which individual ions can move decreases because of interionic attraction and other effects. A graph of total ion concentration versus specific conductance, even for solutions of a single salt, is a straight line only for values below 1,000 micromhos/cm. As specific conductance increases to above 5,000 micromhos/cm, the regression line curves significantly; beyond 50,000 micromhos/cm, the specific conductance may be an unsatisfactory index of ion concentration.

The temperature of the electrolyte affects the ionic velocities and, consequently, the specific conductance. For example, the specific conductance of potassium chloride (KCl) solutions changes about 2 percent per degree Celsius near 25°C.

Specific-conductance meters used in the field should be battery operated, should be equipped with temperature compensator, and should read directly in micromhos/cm at 25°C. The direct reading meter is recommended to save time in converting resistance values to specific conductance and to insure that the value is read in the field.

The cell should be checked before initial use and should be checked daily during regular use. A 0.00702 *N* potassium chloride (KCl) solution (dissolve 0.5234 g KCl dried at 180°C for 1 hour in distilled water and dilute to exactly 1 litre) has a specific conductance of 1,000 micromhos/cm at 25°C. Routine checks are made by using the 0.00702 *N* standard solution at the ambient temperature. The temperature control on the instrument is set at 25°C, and the ambient temperature of the standard KCl solution is recorded. A value of specific conductance is obtained and compared with the values given in figure 6 for the ambient temperature. The value obtained should be within 5 percent of that in figure 6.

Next, the temperature-adjustment knob is moved to the ambient temperature, and the meter is read. The value obtained should be 1,000 micromhos/cm, regardless of the ambient temperature. This procedure checks the temperature compensator, the conductance cell, and the electrical circuit of the instrument.

If the value obtained for the standard solution is not within the specified precision, the cell must be reconditioned and replatinized according to the instructions given in Brown, Skougstad, and Fishman (1970) or in the literature supplied by the manufacturer of the instrument. The carbon-type electrode supplied with some conductance meters needs no platinizing and should be replaced if it fails to perform to the specified accuracy.

Application and interferences

Apparatus

1. Mark V Electronic Switchgear (Chemicon Co.)[1] with cell constants of 0.1 and 1.0 or equivalent direct-reading meter.
2. Thermometer, 0–50°C graduated in 0.1°C.

Procedure

The following general procedure is supplemental to the instructions supplied by the manufacturer:

1. Rinse measuring cell with several volumes of sample water.
2. Bring temperature of cell to that of water being measured by immersing measuring cell in well discharge for at least 5 minutes. Some plastic cells have a high heat capacity and will cause drifting of the reading if not in thermal equilibrium with the sample.
3. Record reading, temperature, time, date, cell constant, and any meter constants.
4. Remeasure, with fresh sample, until reproducible readings are obtained.

Temperature

The temperature of ground water is important for numerous applications. For example, temperature measurements are critical in

[1]The use of brand names in this report is for identification purposes only and does not imply endorsement by the U S Geological Survey

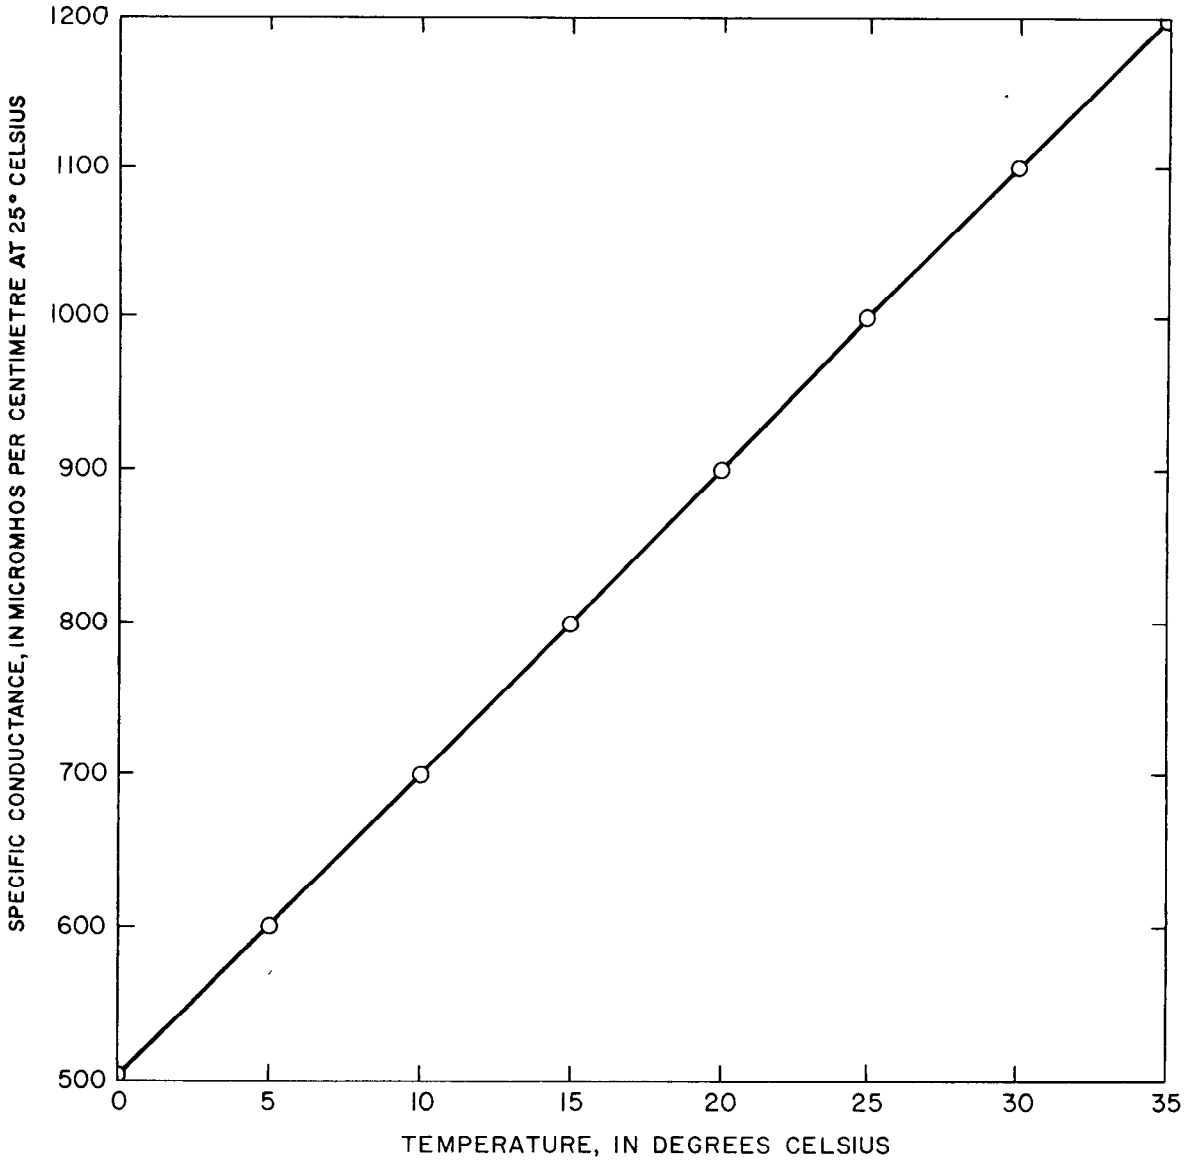

Figure 6 —Specific conductance of a 0 00702 N potassium chloride solution at various temperatures

identifying recharge from nearby surface-water sources. For accurate geochemical evaluation of equilibrium thermodynamics, it is desirable to know the temperature of the water in the aquifer within ±0.1°C.

Summary of the method

The temperature is recorded by a mercury-filled thermometer that is permitted to equilibrate in a sample that is continuously pumped into a dewar flask. The well should be pumped continuously until three identical consecutive readings of temperature are obtained.

Application and interference

The foregoing method may be used to measure the temperature of any ground-water sample but is most accurate when the ambient temperature is within 20°C of the ground-water temperature. New or little-used wells may develop new producing zones during pumping, thereby varying the proportion of

water entering the well from different depths and causing either an instantaneous change or continual drift in the temperature measurements. Drawdown may cause dewatering of certain beds and may cause a change in the temperature. Insufficient pumping time to allow equilibration of water temperature in the casing and pump column will also cause drifting of the temperature.

Apparatus

1. Dewar flask (a "thermos" bottle with a narrow mouth is adequate).
2. Partial immersion thermometer calibrated in 0.1°C or 0.2°F with the usual range of 5–25°C, or any range expected in the ground water in the study area. To minimize breaking the thermometer, steel or brass armor is suggested. The thermometer should be accurate to ±0.1°C as checked against the Bureau of Standards calibrated thermometer.

Procedure

Samples should be collected as close to the wellhead as possible. A continuous stream of water should be conducted through a short plastic tube into the bottom of the flask, allowing a continuous flow of water out of the flask. Readings should be taken after 5 minutes of flow at 1-minute intervals and recorded until no change is observed. If collection by continuous flow is impossible, the sample should be collected in the dewar flask and stoppered, with the thermometer inserted through the access hole. The first sample should be allowed to equilibrate 1 or 2 minutes and should then be discarded. The flask should be quickly refilled, and the temperature should be recorded immediately. This process should be continued until three identical consecutive readings are obtained. A box similar to that shown in figure 7 is useful for carrying equipment and preventing breakage.

pH of solutions

The pH of a solution is a measure of effective hydrogen-ion concentration or, more accurately, it is the negative logarithm of the hydrogen-ion activity in moles per litre:

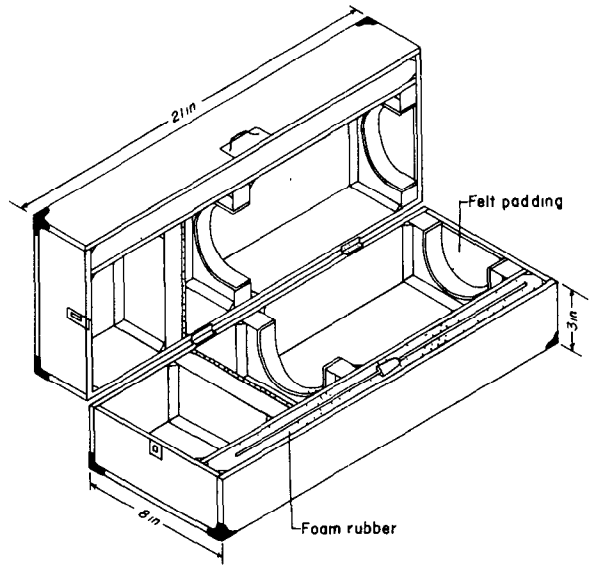

Figure 7.—Carrying box for thermometer, reading lens, and dewar flask

$$pH = -\log [H+].$$

In aqueous solutions, pH is controlled by reactions that produce or consume H+ including practically all dissociations of acids, bases, and hydrolysis. The primary control over pH in most potable ground water is the carbonate system including gaseous and dissolved carbon dioxide, bicarbonate, and carbonate ions. Other dissolved gases, such as hydrogen sulfide and ammonia, can also affect the pH of the solution.

Summary

The pH is determined with a glass hydrogen ion electrode compared against a reference electrode of known potential by means of a pH meter or other potential measuring device with a very high input impedance. A detailed description of pH and reference electrodes and their operations are given in Langmuir (1971), Durst (1969), and Garrels and Christ (1965). Because pH is exponentially related to concentration, great care must be exercised in making a measurement. Details of measurement are given by Barnes (1964).

Interference

A high sodium concentration will give an anomalous pH reading, which must be cor-

rected according to the recommendation of the manufacturer of the pH electrode. This correction is usually necessary only if pH is greater than 11, and sodium concentration is more than 10 moles per litre. Measurement of pH is temperature sensitive, so the standard buffers should be within ±1°C of the sample solution for precise determinations.

Apparatus, reagents, and checklist

1. Orion 401 pH meter or equivalent (a meter with a scale, at least 15 cm long, is necessary for detailed work of ±0.02 pH units).
2. pH buffer solutions 4.00, 7.00, and 10.00; 500 ml each.
3. Corning triple-purpose pH electrode 476021, or equivalent.
4. Orion single-junction reference electrode 90–01, or equivalent.
5. Filling solution for reference electrode.
6. Holder for electrodes, Multiflex or equivalent.
7. Plastic pail.
8. Thermometer.
9. Distilled water.
10. 500-ml plastic squeeze wash bottle for distilled water (color coded so as not to be confused with other reagents in wash bottles).
11. Box of small Kimwipes or equivalent.
12. Mixed bed deionizer in a delivery tube, 16-ounce size Deeminac or equivalent (useful for final treatment if commercial distilled water must be purchased).
13. Three 100-ml plastic beakers.
14. One 250-ml plastic beakers.
15. Card table or other portable table on which to work.

Procedure

The following procedure has been found useful in supplementing the pH meter manufacturer's instructions:

1. Check and fill reference electrode with internal filling solution recommended by the manufacturer. On Orion reference electrode, press cap and permit some of the filling solution to drain from the electrode to insure complete electrolite contact before inserting electrode in sample.
2. Adjust buffer solution and electrodes to ±1°C of the sample temperature by letting sample water run over submerged bottles and electrodes. (Be careful not to let sample water enter the filling hole of the reference electrode.) To prevent floating of partially filled buffer bottles, epoxy heavy steel washers to the bottom of the bottles. Alternatively, a small water bath can be constructed that holds two buffer bottles and sample beaker firmly in place during determination (fig. 8).
3. Record temperature of water.
4. Level meter and check to insure that the needle is properly adjusted.
5. Place 7.00 buffer in color-coded insulated beaker and place electrodes in the buffer. The pH of the buffer is equal to 7.00 only at 25°C; therefore, it is necessary to use the temperature-correction curve supplied by the manufacturer. Figure 9 is an example of a typical curve of temperature versus pH for a commercial buffer of pH 7.00. Turn on meter and adjust to correct pH value. If the electrodes have not been used recently, or have been allowed to dry for several days, it may take 10–20 minutes for them to stabilize. If electrodes will not stabilize, try either a new reference or pH electrode. To keep electrode from drying out and ready for use, the electrode tip should be immersed in a rubber or plastic sack (such as the finger cut from a plastic glove) in which has been placed a few millilitres of buffer solution.
6. Turn meter off or to standby position and remove electrodes from 7.00 buffer. Rinse thoroughly with distilled water and blot dry. Place electrodes in either pH 4.00 or pH 10.00 buffer, bracketing the expected pH of the sample. Switch on meter and allow several minutes for stabilization to occur before making final adjustment. Turn meter to off or standby position.
7. Check adherence of the response of the electrodes to the theoretical Nernst slope. According to manufacturer's instructions, and before adjusting meter with pH 7.00 buffer, the slope indicator is set to 100 percent, and the temperature compensator is set to the correct temperature (of water and buffer). After the electrode is placed in the second buffer, the temperature compensator is adjusted until the correct value of the second buffer is obtained.

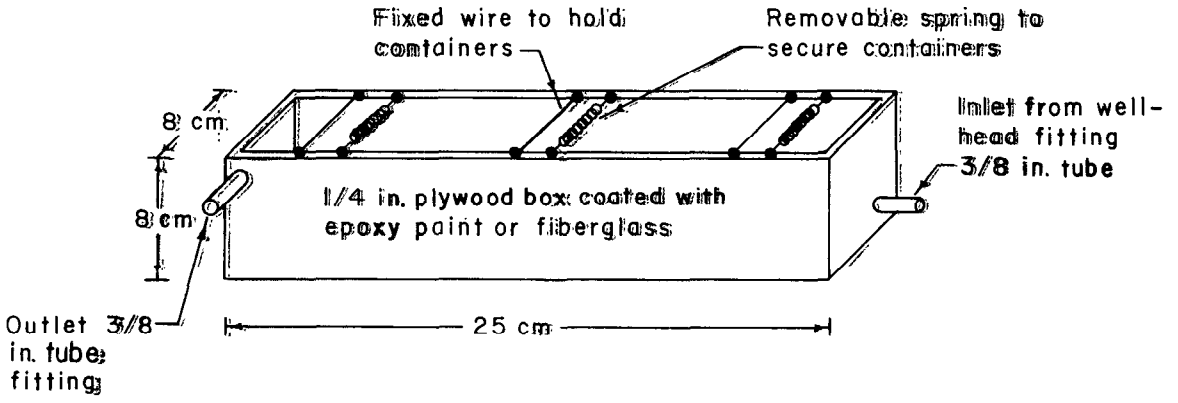

Figure 8.—Portable water bath for maintaining buffers and sample at wellhead temperature.

Then the slope indicator is adjusted until the temperature compensator points to the temperature of the solution. The percentage of theoretical slope can now be read on the slope scale.

Experience has shown that if the observed percentage differs from the theoretical value by ±10 percent, the reference electrode should be replaced and the slope rechecked by repeating steps 5–8. The theoretical Nernst slope for temperatures commonly encountered in ground water is shown in figure 10. Comparison of electrode response to the theoretical response (Nernst equation) is a check on the efficiency of the electrode system. The lack of agreement between the observed electrode system and the Nernst equation does not indicate that the observed pH values are inaccurate. All that is indicated is a potential source of trouble and some part of the system is not operating as efficiently as it should. Generally, combination pH-reference electrodes do not conform to the theoretical curve as closely as do the individual electrodes.

8. Rinse electrode with distilled water and blot dry. Recheck value of pH 7.00 buffer. If value is within ±0.02 pH of the correct value, proceed with next step. If drift from original setting has occurred, repeat steps 5–8.

9. Thoroughly rinse electrode with sample water and then place electrodes in a sample collected in a 250-ml plastic beaker. Turn on meter. Do not swirl or stir sample. Allow at least 2 minutes for equilibration. Record value. Turn meter to off or standby position. Repeat

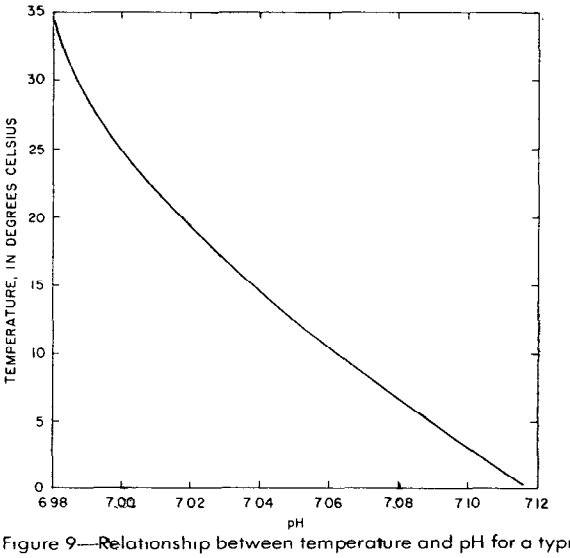

Figure 9—Relationship between temperature and pH for a typical commercial buffer solution

step 9, using newly collected samples until three consecutive readings differ by no more than ±0.02 pH unit. If equilibrium is not attained in several minutes, out gassing of CO_2 may be occurring. In such cases the initial reading may be the best. Out gassing may be reduced if the electrode system is placed through a tightly fitting stopper into the water-filled beaker.

10. Place electrodes in temperature equilibrated buffer 7.00. Turn on meter. If reading is within ±0.02 of original buffer reading, then analysis is complete. Turn meter off or to standby position. If reading has changed from original value, repeat steps 5–10. NOTE: In

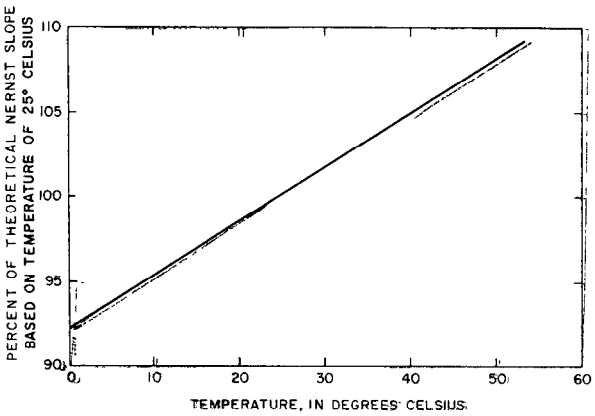

Figure 10.—Relationship between temperature and the Nernst slope.

dry windy climates, such as in the southwestern United States, a static charge tends to build on the plastic face of a pH meter, which causes erratic movement of the indicator needle. Antistatic spray, of the type used for phonograph records, sprayed on the meter face will minimize this interference. It is also desirable to keep the meter protected from extreme temperature changes during measurement, as this will affect the stability of the electronic system and consequently the precision of the measurement. In cold waters, slow electrode response may occur from the precipitation of the saturated filling solution in the reference electrode, thereby reducing the fluid contact. This can be remedied by allowing the filling solution to reach ambient temperature before filling the reference electrode.

Carbonate and bicarbonate

For chemical equilibrium calculations related to carbonate minerals, it is essential to have an accurate value for pH, carbonate, and bicarbonate concentrations. Carbonate and bicarbonate determinations for ground water must be made in the field at the time of sampling if the concentrations are to accurately represent those originally present in the water. These parameters are particularly subject to change if the sample is collected and stored in certain types of plastic bottles that are permeable to carbon dioxide.

Summary of the method

Detailed descriptions of the theory and practice of potentiometric titration of carbonate and bicarbonate is given in Barnes (1964), Weber and Stumm (1963), and Brown, Skougstad, and Fishman (1970). In general, the carbonate (CO_3^{-2}) and bicarbonate (HCO_3^-) concentrations are determined by titration of the water sample with a standard solution of strong acid. The following equations govern the reactions involved:

(1) $CO_3^{=} + H^+ \Longleftrightarrow HCO_3^-$

(This reaction is complete near pH 8.3)

and

(2) $HCO_3^- + H^+ \Longleftrightarrow H_2O + CO_2$,

(This reaction is complete near pH 4.5)

The end point of the carbonate or bicarbonate titration process is determined from (A) a plot of pH versus titrant volume, where the end point corresponds to an inflection point of the curve (fig. 11) or (B) a plot of

$$\frac{\Delta \text{ pH}}{\Delta \text{ ml of titrant}}$$

the rate of change in pH per unit volume of titrant versus the average titrant volume between two successive values. The end point is the value at which occurs the maximum rate of change of pH per volume of titrant added (fig. 11).

The approach in (B) is less subjective and permits consistent choice of the end point, but requires exacting analytical procedures and the assurance of complete equilibration of pH after each increment of acid added.

Salts of weak organic and inorganic acids, such as silica, which cannot be corrected for, may yield erroneous results when present in large amounts. In addition, oils, greases, and colloidal material, if present, may tend to foul the pH electrode and prevent its proper operation.

Apparatus and reagents

1. All equipment and reagents used for pH determinations. (See section on pH determination.)

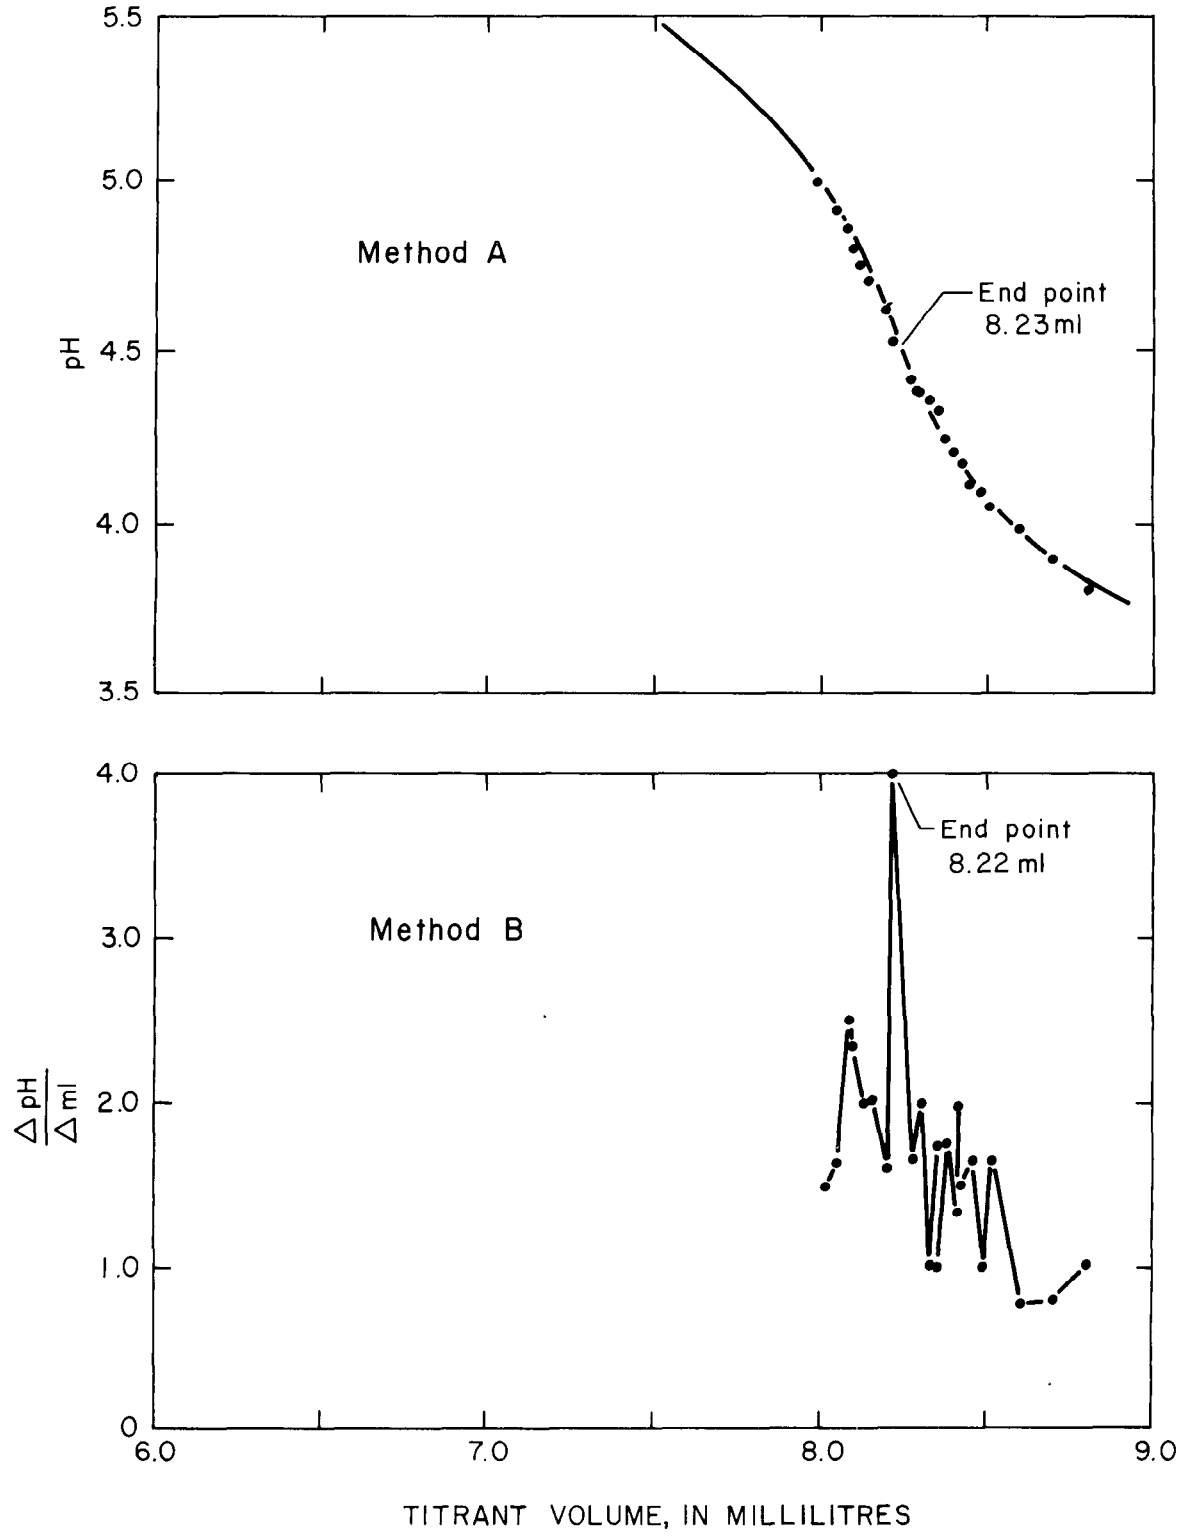

Figure 11.—Two methods of determining the end point for bicarbonate determinations.

2. Buret, 25-ml capacity with 0.1-ml graduation and Teflon stopcock.

3. Portable battery-powered magnetic stirrer, Lapine or equivalent with extra batteries.

4. Teflon coated stirring bar, small size.

5. Ring stand, clamp holder, and universal V-jawed clamp.

6. 25- and 50-ml class A volumetric pipets.

7. 250-ml plastic-squeeze acid bottle with nozzle for filling buret (color-coded bottle to prevent confusion with distilled water bottle).

8. 1 litre of 0.01639 *N* sulfuric acid packaged in two 500-ml plastic bottles to prevent breakage. (Prepared according to Brown and others, 1970).

9. Wire pen cleaner for dislodging foreign debris in buret tip.

10. Cap to prevent dust from entering buret.

11. Buret meniscus reader (useful for poor light conditions often encountered in the field).

A padded wooden box (fig. 12) is useful for carrying volumetric glassware and small accessories such as meniscus reader, stirring bar, wire pen cleaner, and so forth.

Procedure

1. Adjust temperature of titrant to ±2°C of the sample by immersion of securely stoppered acid-storage bottles in a water bath of the sample fluid; set up and fill buret to 0.00 ml; cap buret with dust cover.

2. From a pressure-filtered sample (see section on filtration) pipet 50 ml into a clean dry 100-ml beaker. Under no circumstances should the sample be diluted or concentrated in any way. The pipet is rinsed three times with the sample water before final sample is placed in the beaker. If titration cannot be completed with one filling of the buret, discard sample and use a smaller sample size. There is a great chance for error in refilling a buret during a titration.

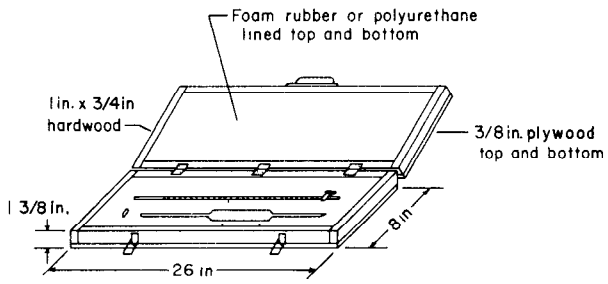

Figure 12 —Carrying box for volumetric glassware electrodes and other small fragile items.

3. Insert pH and reference electrodes into the sample. The electrodes should be calibrated in 7.00 and 4.00 buffer solutions at the temperature of the sample, then washed in sample or distilled water and blotted, not wiped, dry. (See section on pH determinations.) Insert the clean dry stirring bar and adjust stirrer to slow speed.

4. If pH is greater than 8.3, add sulfuric acid by drops, recording volume accurately with 0.05-ml increments and pH values to 0.02 pH units until pH is below 8.00 (See table 2 for useful recording format.)

When the pH of sample during titration declines below 8.00, or the initial value is less than 8.3, add acid in increments of 1 ml and record pH value at each increment. Continue this procedure until pH declines to approximately 5.5. From pH 5.5 to pH 4.0, add acid by

3 90	8.70	.80
3 80	8.80	1.00

drops, recording pH at each volume increment. The most sensitive part of the titration is usually between 4.8 and 4.3. Adding acid in fractions of a drop is desirable in this range. (Carefully touch ¼ or ½ drop to sample surface and pull away from buret tip.) Allow 15–20 seconds for equilibration.

Calculations

Calculations for the carbonate content are made by using the equation

$$CO_3^{=} \text{ in mg/l} = \frac{1{,}000}{ml_{(s)}} \times (ml_{(a)} \text{ to end point near pH 8.3}) \times (0.9835).$$

Calculations for bicarbonate are made by using the equation

$$HCO_3^{-} \text{ in mg/l} = \frac{1{,}000}{ml_{(s)}} \times (ml_{(a)} \text{ between end points near 8.3 and 4.5} - (ml_{(a)} \text{ to end point near 8.3}),$$

where $ml_{(a)}$ and $ml_{(s)}$ = volumes of standard 0.01639 N sulfuric acid and samples, respectively, and end points are determined as in figure 11. Because of the relatively small amount of time required for this analysis, it is best to repeat titration to insure precision.

Eh (Oxidation-reduction potential)

A chemical reaction in which an element undergoes a loss or gain of orbital electrons is referred to as oxidation or reduction and may be represented by the following general expression:

$$\text{reduced species} \rightarrow \text{oxidized species} + ne^{-},$$

where ne- is the number of electrons involved per atom. The standard oxidation potential, $E°$, for a half-cell reaction of this type is the potential that would occur if the two species are both present at unit activity at 25°C and one atmosphere pressure. When the activities of participating species differ from unity, the potential observed at equilibrium is termed the redox potential (oxidation-reduction potential). The redox potential, represented by the symbol Eh, is related to the standard potential and the activities of participating substances by the Nernst equation:

$$Eh = E° + \frac{RT}{nF} \ln \frac{\text{oxidized state}}{\text{reduced state}},$$

where $E°$ is the standard potential of the reaction, R is the universal gas constant, T is the absolute temperature in degrees Kelvin, F is the Faraday constant, n is the number of electrons involved in a half-cell reaction, and $\ln \frac{\text{oxidized state}}{\text{reduced state}}$ is the natural logarithm of the ratio of the products of the activities of oxidized species to that of the reduced species. The potential is reported as volts or millivolts, relative to the potential of the hydrogen electrode, taken as zero, and may be positive or negative (the greater the negative value, the more the reducing tendency of the system). An excellent review article on Eh-pH determination has been presented by Langmuir (1971).

Some writers have preferred the notation "pE," defined as the negative logarithm of the molar activity of the electrons, which avoids some of the unit conversion calculations required by the Nernst equation (Stumm, 1966).

Eh is generally a qualitative tool for the ground-water geochemist. However, it has been used very effectively in explaining the concentration of many minerals that exhibit more than one oxidation state under natural conditions. See, for example, the relation of iron in natural water to Eh as shown by Back and Barnes (1965).

Summary of the method

Eh is measured with a noble metal (usually platinum) and a reference electrode system using a pH meter that can be read in millivolts. Reference solutions with known Eh are used to obtain the potential and to check the accuracy of the electrode system. Unlike pH buffer solutions, the Eh reference solutions are not used to adjust the system to the correct range of values. The potassium ferric-ferro cyanide solution described by ZoBell (1946), which has been proved satisfactory as a standard reference solution by many geochemists, is the standard recommended in this manual.

At 25°C, the potential of the ZoBell solution relative to the standard hydrogen electrode is +0.428 volts. The potential varies with temperature according to the following equation:

$$Eh = 0.428 - 0.0022\ (t-25)\ \text{volt}$$

(Ivan Barnes, oral commun., 1972).

At 25°C, the saturated calomel (mercury-mercurous chloride) reference electrode, which is commonly used, has a reference voltage of +0.244 volts relative to the potential of the standard hydrogen electrode. The voltage varies with temperature according to the following equation:

$$Eh = 0.244 - 0.00066\ (t-25)\ \text{volt}$$

(Garrels and Christ, 1965, p. 127),

where t is the temperature in degrees Celsius.

By combining the half-cell potentials for the platinum-calomel electrode system and ZoBell solution and utilizing the equations for potential variation with temperature (emf = $Eh_{ZoBell} - Eh_{Calomel}$), the theoretical potentials for the system at different temperatures can be calculated. The relationship of theoretical potentials of this system to temperature is shown in figure 13. The relationship for a silver–silver chloride reference electrode and platinum electrode system to temperature is also plotted in figure 13.

The measurement of Eh of a system requires that the observed potential be adjusted to a potential relative to the standard hydrogen electrode.

In equation form,

$$Eh_{Sys} = E_{obs} + Eh_{ZoBell+ref} - E_{ZoBell\ (obs)},$$

where

Eh_{Sys} = The true Eh of the environment, relative to the standard hydrogen electrode,

E_{obs} = the observed potential of the environment, relative to the reference electrode,

$Eh_{ZoBell+ref}$ = the theoretical Eh of the reference electrode and ZoBell solution, relative to the standard hydrogen electrode, and

$E_{ZoBell(obs)}$ = the observed potential of ZoBell solution, relative to the reference electrode.

Application and interferences

Redox potential measurements in laboratory solutions where activities of oxidized and reduced species may approach unity can be expected to match theoretical calculated potentials reasonably well. Experience has shown that many natural water systems do not give measured Eh values that can be quantitatively interpreted. Measurements made in water containing dissolved oxygen, for example, give values lower than might theoretically be expected. Garrels and Christ (1965) attribute this to a slow, rate-determining step in the reaction of aqueous oxygen with other ions. If dissolved oxygen (DO) is above 0.01 mg/l, the DO determination may be more useful than attempting to determine Eh. It is also generally useless to try to measure Eh in systems containing hydrogen sulfide.

Back and Barnes (1965) were able to correlate measured redox potentials with dissolved ferrous iron contents of ground water in moderately reducing systems. Most other experiences with Eh measurements that are described in the literature lead one to conclude that the measurement is primarily a qualitative tool. It may give useful information about systems whose solid and solute components are reasonably well known from other kinds of

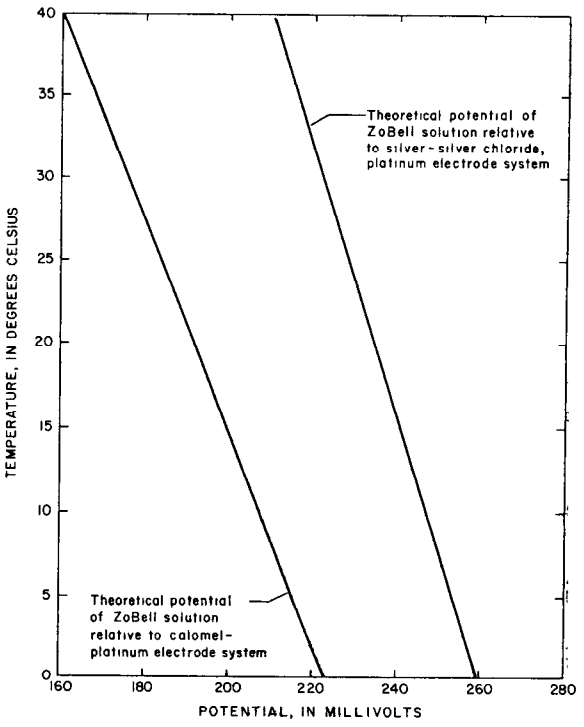

Figure 13.—The potential of ZoBell solution, relative to reference-electrode systems, at various temperatures

measurements. Limitations and uncertainties inherent in Eh measurements were discussed by Stumm (1966) and Doyle (1968). Charged colloidal material and differences in composition and concentration of the unknown and reference solutions may create errors. Oil and grease may coat the noble-metal electrode, preventing contact with the sample.

Apparatus and reagents

1. Orion 401 specific-ion meter or equivalent.
2. Orion combination electrode 96–78–00 or equivalent and Orion electrode filling solution 90–00–01 or equivalent. (Thimble platinum and separate reference electrodes are also suitable.)
3. ZoBell reference solution:

Dissolve

1.4080 g of potassium ferrocyanide $K_4Fe(CN)_6 3H_2O$ (0.00333*M*)

1.0975 g of potassium ferricyanide $K_3Fe(CN)_6$ (0.00333*M*)

7.4555 g of potassium chloride KCl (0.10*M*)

in distilled water to make 1 litre. This solution is stable for several months but should be kept in a black plastic bottle and out of sunlight as much as possible. It has a standard potential of +428 millivolts at 25°C. This solution is poisonous and should be handled with care.

4. Ring stand, clamp holder, and universal V-jawed clamp.
5. Eh cell (fig. 14).
6. Plastic 100-ml beaker.
7. Water bath for ZoBell solution (plastic pail or bottom half of a 1-gallon plastic bottle).
8. Thermometer.
9. Equipment for measuring dissolved oxygen.
10. Small strips of crocus cloth for polishing platinum electrode.

Procedure

1. Fill combination electrode with proper filling solution (Orion 90–00–01 or equivalent). Depress body and let some of the fluid drain to waste. Bring ZoBell solution to the temperature of sample by allowing sample to flow over closed bottle. Record temperature. While the ZoBell solution is equilibrating to the sample temperature, determine the presence of dissolved oxygen in the water sample. If dissolved oxygen is greater than 0.05 mg/l, do not proceed with the Eh measurement. If dissolved oxygen is absent, proceed with step 2.

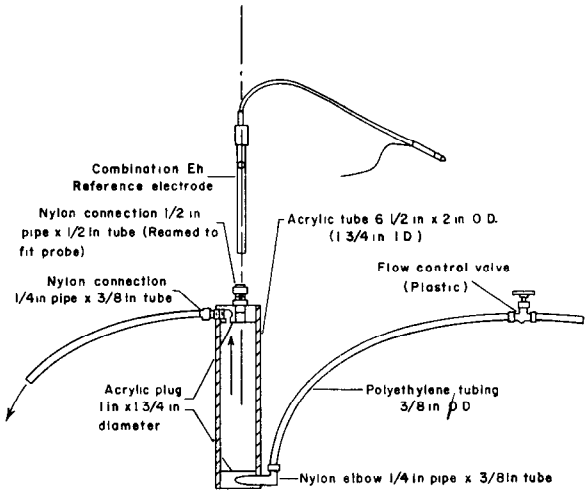

Figure 14 —Eh measuring cell

2. Place combination electrode in the ZoBell solution that has been equilibrated to the sample temperature. Plug electrode leads into meter and turn function switch on meter to millivolt mode. Allow several minutes for electrode to equilibrate while maintaining the bottle of ZoBell solution in the water bath. Record reading. If reading differs by more than 10 millivolts from the theoretical value at that temperature (fig. 13), replace reference electrode fluid and repeat measurement. If that procedure will not bring the reading within 10 millivolts of the theoretical value, polish the platinum end of the electrode with a piece of crocus cloth and recheck reading. If this procedure fails, the electrode should be replaced. If reading is within ±10 millivolts of the theoretical value, rinse electrode with sample water and proceed with step 3.

3. Place electrode in the plastic Eh cell pointing up (fig. 13) and let the water flow through the cell. Filler hole in side of electrode should be above the top of Eh cell. Make sure all air bubbles are removed from the system. Use control valve on inlet to insure that the head of sample is below level of reference solution of the electrode or some of the sample will be forced into the reference electrode and

change the potential of the system. Clamp Eh cell onto the ring stand.

4. Turn function switch on meter to millivolt mode and allow the water to flow through the cell until the readings stabilize. Stabilization usually occurs within 20 minutes but may require as much as an hour or more. Turn off sample flow to prevent any streaming potential and immediately record meter reading. This is the observed Eh of the sample, or more specifically, the observed full-cell emf relative to the reference electrode.

5. Record the data and calculate the Eh relative to the standard hydrogen electrode as follows:

Data record

A. Temperature of sample _____
B. Observed potential, in millivolts, of ZoBell solution, relative to reference electrode, at sample temperature _____
C. Theoretical potential, in millivolts, of ZoBell solution, relative to reference electrode, of sample temperature (fig. 13) _____
D. Theoretical potential, in millivolts, of reference electrode system and ZoBell solution, relative to the standard hydrogen electrode, at sample temperature (fig. 15) _____
E. Observed potential of sample, in millivolts _____

Calculations

I Checking the electrode

Calculate difference between observed potential and theoretical potential of ZoBell solution, relative to reference electrode,

$$B - C = \text{difference}.$$

If this difference is less than ±10 millivolts, proceed with next step. If difference is greater than ±10 millivolts, see step 2 of procedure for remedial measures.

II Calculate the Eh of the system

E−B+D=Eh value of the system. Report Eh value [either positive (+) or negative (−)] to nearest 10 millivolts.

A field example may help to clarify the procedure:

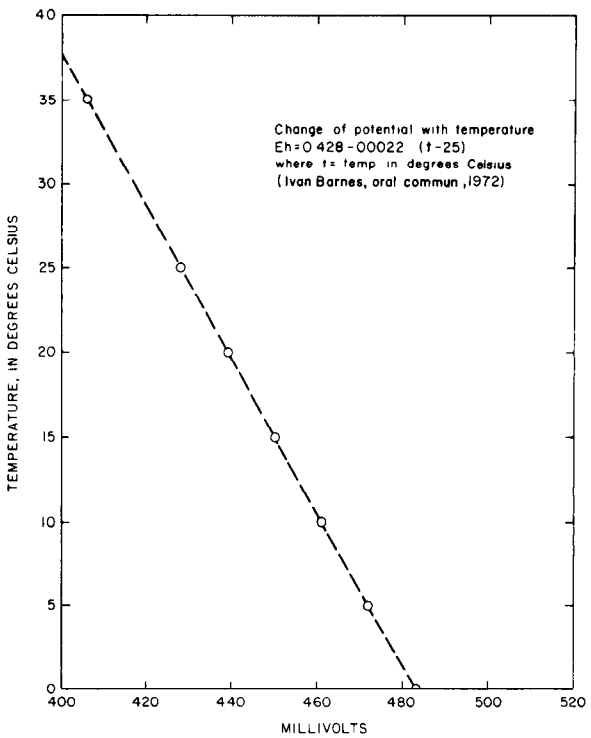

Figure 15.—The potential of ZoBell solution, relative to the standard hydrogen electrode, at various temperatures.

October 6, 1971 @ 0930, St. Paul, Minnesota; G. Ehrlich, H. Reeder, W. Wood
Well 2–N, artificial-recharge site 539 feet deep, 6-inch diameter, finished in the Prairie duChein
Pumping 10 gal/min for 22 hours
Temperature of water from well is 10.0°C

The observed potential of ZoBell solution, relative to the combination reference–platinum electrode, at 10°C was +215 millivolts. (Theoretical potential for ZoBell solution, relative to this electrode system, at 10.0°C is +207 millivolts (fig. 13). The 8-millivolt difference was considered small, and the decision was made to proceed with the measurements.) The observed potential of the water sample after system stabilized in 30 minutes was −120 millivolts.

Data record:

A. Temperature of sample _____ 10°C
B. Observed potential, in millivolts, of ZoBell solution, relative to reference

electrode, at sample temperature ---- +215

(C. Theoretical potential, in millivolts, of ZoBell solution relative to reference electrode, at sample temperature (from fig. 13) ---------- +207

(D. Theoretical potential, in millivolts, of reference electrode system and ZoBell solution, relative to standard hydrogen electrode, at sample temperature (fig. 15) ---------- +461

(E. Observed potential of sample, in millivolts ---------- −120

(Calculations:

(I. B−C=(+215)−(207)=+8 millivolts

(II. Eh_{sys}=E−B+D=(−120)−(215)+(461)=+126 millivolts

(Report at +130 millivolts.

Dissolved oxygen

Oxygen dissolved in ground water usually is derived from contact with the atmosphere before recharge to the aquifer. The solubility of oxygen in water is dependent upon the partial pressure of oxygen in the atmosphere, the dissolved solids, and the temperature. The experience of the author has indicated that the presence of dissolved oxygen in ground water is a more common occurrence than is generally believed. This is particularly true in hydrologically stressed systems. Dissolved oxygen can exist at great depths in aquifers which have little or no oxidizable material in the water flow path and can also be present in any aquifer where the water's residence time is short compared to the rate of oxygen consumption.

Summary of the method

Methods commonly used for the determination of dissolved oxygen are described in "Standard Methods for the Examination of Water and Wastewater" (American Public Health Association and others, 1971). Some of these methods are subject to rather serious interferences. Regardless of the method used, great care must be taken to prevent atmospheric aeration of the sample during collection and analysis. Use of a flow chamber to prevent contact of the sample with the atmosphere and use of a portable dissolved-oxygen meter for analysis eliminates or minimizes the effects of most interferences and yields a continuous record of dissolved oxygen during the pumping of a well.

The sensing element of the dissolved-oxygen meter is basically a polarographic system in which two solid metal electrodes in contact with an electrolyte are separated from the test solution by an oxygen-permeable membrane. The membrane serves as a diffusion barrier against impurities. The rate that oxygen diffuses through the membrane is proportional to the pressure differential across the membrane. When oxygen diffuses through the membrane, it is rapidly consumed at the cathode. Thus, the rate of diffusion is proportional to the absolute pressure of oxygen outside the membrane. When a suitable polarizing voltage is applied across the cell, the consumption of oxygen at the cathode causes a current to flow through the cell. This current is directly proportional to the quantity of oxygen consumed.

For precise dissolved-oxygen determinations, the meter should be calibrated before each use. Preferably, the calibration should be accomplished on the water under test. One sample of the water should be deoxygenated by adding an excess of sodium sulfite; a second sample should be aerated to saturation. The dissolved-oxygen concentration of the air-saturated sample can be determined from figures 16 and 17, provided the water temperature, barometric pressure, and altitude of the sampling site are known. In the absence of interferences, a more precise dissolved-oxygen value for the aerated sample can be determined by use of the Alsterberg azide modification of the Winkler method (Brown and others, 1970, p. 126) or any approved modification of this technique. Where interfering substances are suspected, calibration should be accomplished on distilled water aerated to saturation.

The meter must be precisely calibrated according to the manufacturer's instructions before each use. In general, satisfactory calibration can be accomplished by using air-saturated water. In this procedure, the water sample is aerated by being shaken in the presence of air for 15–20 minutes (a 1-litre uncapped narrow-mouthed bottle half full works well) or by using a battery-powered aerator for

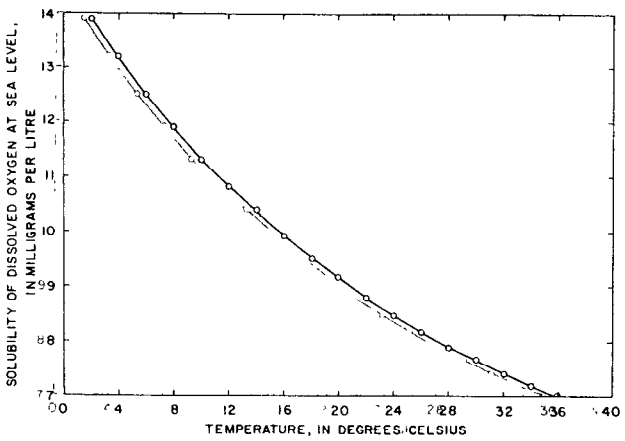

Figure 16.—Solubility of oxygen in water at sea level as a function of temperature.

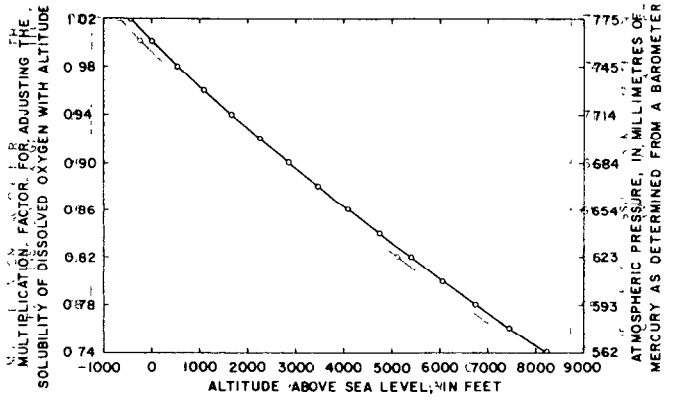

Figure 17.—Correction factor for the solubility of oxygen at different atmospheric pressures and altitudes.

5–10 minutes. Temperature of the water is then measured. Figure 16 shows the dissolved-oxygen concentration of air-saturated water at sea level as a function of temperature. Figure 17 shows correction factors that must be applied to the apparent oxygen concentration when the atmospheric pressure varies from 760 mm of mercury. By use of these figures, the correct value of oxygen dissolved in the air-saturated sample can be obtained and the meter calibrated.

Application and interferences

The membrane-electrode method is applicable for the measurement of dissolved oxygen in any well or spring from which a sample can be collected without aeration.

Oxygen-permeable membranes used for the electrode system are permeable to a variety of other gases, none of which is easily depolarized at the indicator electrode. In addition, the concentrations of most of these gases in ground water probably are too small to cause significant interference with dissolved-oxygen determinations. However, use of the membrane electrode in water containing such gases as hydrogen sulfide without loss of sensitivity requires frequent changing of the membrane, replacement of the electrolyte, and recalibration of the electrode.

Apparatus and reagents

11. Yellow Springs model 54 ARC oxygen meter with sensor, or equivalent.
2. Flow chamber with flow control valve (fig. 18).
3. Ring stand, clampholder and universal V-jawed clamp.
4. Bottle of electrolyte for the sensor.
5. Extra membranes for the sensor.
6. Thermometer.
7. Two 8-ounce plastic bottles.
8. 1-litre plastic bottle for aeration of the reference sample.
9. Battery-operated aerator.

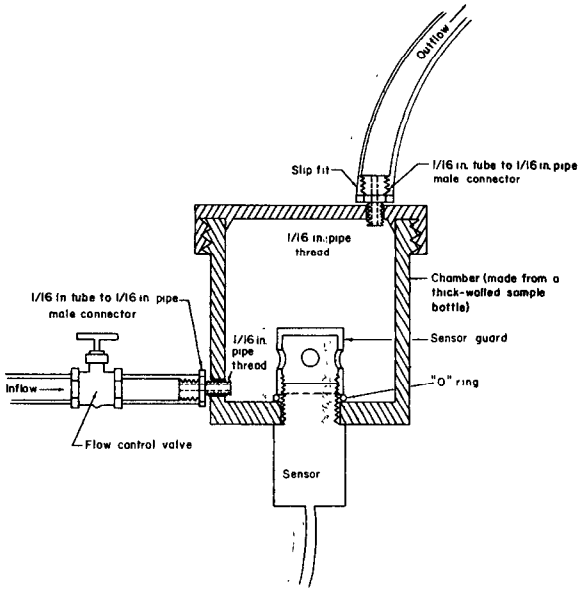

Figure 18.—Flow chamber for determination of dissolved oxygen from a pumped well.

10. Battery-operated magnetic stirrer and stirring bars.
11. Saturated solution of sodium sulfite.
12. Cobaltous chloride solution.
13. Reagents and plasticware for Alsterberg azide modification of Winkler method for dissolved-oxygen determination (Brown and others, 1970, p. 126).

Procedure

1. Pour sample into an 8-ounce plastic bottle to which has been added several millilitres of saturated solution of sodium sulfite and a trace of cobaltous chloride. Replace cap and stir on magnetic stirrer for several minutes.
2. Prepare oxygen meter for calibration according to manufacturer's instructions.
3. Switch meter to the 0–10 position. Remove sensor guard and insert the sensor in deaerated sample. If dissolved oxygen in sample is greater than 0.0 mg/l, add saturated sodium sulfite in small increments until a reading of 0.0 mg/l is obtained. Add an excess of several millilitres after a reading of 0.0 mg/l is obtained.
4. Pour a second sample into a 1-litre plastic bottle and aerate for 5–10 minutes with battery-operated aerator.
5. Determine the dissolved-oxygen concentration on an aliquot of the aerated sample by the Alsterberg azide method (Brown and others, 1970, p. 126). If the barometric pressure is known, the dissolved-oxygen concentration of the air-saturated sample can be determined from figures 16 and 17.
6. Pour an aliquot of the aerated sample into a clean 8-ounce plastic bottle. Switch meter to the 0–10 position and insert the sensor in aerated sample. Adjust speed of magnetic stirrer until maximum reading is obtained.
7. With the calibration control, adjust the dissolved-oxygen reading to the value obtained by step 5.
8. Place sensor in the flow chamber (fig. 18). Place the "O" ring over the sensor, being careful not to disturb the membrane. Replace sensor guard and tighten until the "O" ring is depressed very slightly. Place the top on the flow chamber and gently open the flow control valve. Measure the dissolved-oxygen concentration at about 5–10 minute intervals until a stable reading is obtained. Record the value to the nearest 0.1mg/l.

Downhole Pressure and Temperature Gauge

PERFORMANCE PARAMETERS:
(EXCLUSIVE OF THREADS)

TRANSDUCER	SHEAR MODE QUARTZ
TRANSDUCER RATING	10,000 PSI
PRESSURE RANGE	15-11,000 PSI
TEMPERATURE RATING (OPERATING)	-99.4 TO 302°F (-73 TO 302°C)
TEMPERATURE SHOCK	5.4°F (3°C) PER MINUTE
VIBRATION	>10 G, 10 HZ - 2 KHZ
SHOCK	500 G
PRESSURE MEASURE RANGE (CALIBRATED)	200 -10,000 PSI
PRESSURE ACCURACY	±0.015% 1.5 PSI (AT FULL SCALE)
PRESSURE RESOLUTION	0.0001
PRESSURE STABILITY	±0.02% FULL SCALE, 2.0 PSI/YEAR
TEMP MEASUREMENT RANGE (CALIBRATED)	77 TO 302°F (25 TO 302°C)
TEMPERATURE ACCURACY	0.27°F (0.15°C)
TEMPERATURE RESOLUTION	0.0001°F
TEMPERATURE STABILITY	0.018°F (<0.01°C) PER YEAR
MAX SAMPLE RATE/SECOND	>16
TOOL ADDRESS	T1/T2

1 Introduction

The SureSENS™ QPT ELITE tools are pressure/temperature gauges suitable for single or multipoint reservoir monitoring in either single or multiple-gauge configurations. The gauge is highly robust, ensuring mechanical integrity by deep-penetration and high-vacuum, electron-beam fusion welds, without the need for filler material.

2 Description

The Baker Hughes Company SureSENS QPT ELITE gauge for permanent downhole installations measures static and dynamic pressures and temperatures with introducing a step change in reliability and accuracy. The gauge is qualified for operation at pressures less than 35,000 psi (2,413.1 bar) and temperatures up to 437°F (225°C).

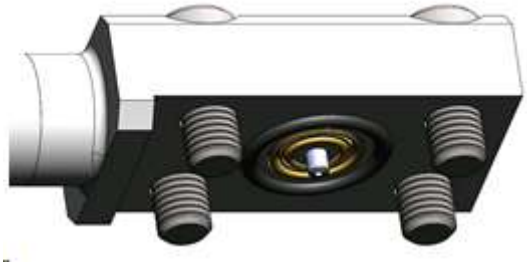
The static pressure information obtained can be used to determine production performance, calculate reserves, and provide input to reservoir simulations. The dynamic pressure data can help determine reservoir characteristics and optimize production rates.

The SureSENS QPT ELITE gauge includes the new ELITE electronics package, built upon our industry leading STAR hybrid electronic package design. The ELITE electronics package incorporates an application specific integrated circuit (ASIC), providing a new level of reliability to the industry.

3 Application

The cost-effectiveness and flexibility of the SureSENS system enables deployment in single- or multiple-gauge applications and is especially suited to downhole applications, which have bottomhole pressures of less than 35,000 psi (2,413.1 bar) and bottomhole temperatures of less than 437°F (225°C). The applications can be tied back to a surface or floating facility, or interfaced with a subsea infrastructure. The flexibility of the system enables the selection of a number of parameter measurements, including single-point zonal pressure measurements to multiple-point pressure measurements (multiple zones or intelligent applications), as well as applications where differential pressure measurements are required (e.g., fluid characterization or flowmeter applications).

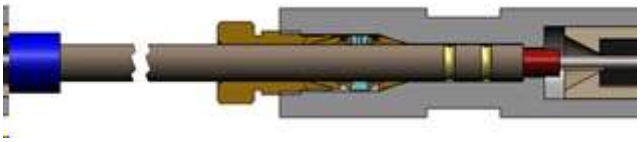
4 Features and Benefits



- ELITE electronics package
  - Provides superior reliability in demanding high-pressure/high-temperature (HP/HT) conditions.
- Flexible, compact design
  - Easily change gauge and pressure porting configurations without modifying the carrier.
  - Multiple gauge combinations can be deployed on single standardized carrier.
- Unique construction configurations with less connections
  - Eliminates the need for additional splices.
  - Increases reliability.
  - Reduces installation time.

Uncontrolled when printed or transmitted electronically
FOR INTERNAL USE ONLY
Baker Hughes Company – Confidential

- Supports multiple monitoring devices on single tubing encapsulated conductor (TEC) cable
  - Deploys multiple gauges, flowmeters, and valve positions to provide redundant readings.
  - Serves as platform for future developments.
- Proprietary counting method and broad sample gate duration
  - Derives finest P/T measurement resolution attainable.



Pressure Interface Manifold

The gauge pressure interface connection to the carrier are dual metal C-rings that can be externally tested in the direction which it will experience pressure, eliminating the need for an internal pressure test tool.

Cable Head

The TEC's primary seal is a dual metal-to-metal pressure-testable interface, and the mechanical package is completely integrated into the gauge assembly, which eliminates the requirement for external Y-block components.

Gauge Addressing

The SureSENS QPT ELITE gauge supports multiple node addresses that range from 1–32 with a maximum of 32 gauges in multidrop applications. For these applications, the bottom gauge will not require a feed through. All other gauges above the bottom gauge deployment will require a TEC feedthrough which connects each gauge in the well without the use of a Y-splice assembly.

Each gauge has its own unique address expressed in the nomenclature T1, T2, T3, etc. Default tool addressing will be Single – T1, Dual – T1/T2, Triple – T1/T2/T3.

Example: If three dual gauges were to be deployed in the same well, all six tools must have an individual tool address, this would require three different material numbers to be ordered* as shown in address designation for multidrop application (Table 1).

Table 1: Address Designation for Multidrop Application

Example Configuration	Tool Address
Dual gauge 3 with feedthrough	T5/T6
Dual gauge 2 with feedthrough	T3/T4
Dual gauge 1	T1/T2

Note: Tools with the same addresses cannot be run on a single TEC system.

*Refer to product selection chart (Table 6) for information on tool addresses.

Ordering Guide

Deliverables

All orders for SureSENS QPT ELITE gauges will have the following items delivered:

- SureSENS QPT ELITE gauge
- Certificate of conformance (COC)

Note: All installation kits and redress kits are ordered separately.

Note: Coefficient files and calibration information are available at go/gauge.

Table 3: Accessory Equipment

Material	Description
10456966	Opposing ferrule seal (OFS) install kit
10456879	Manifold install kit
H0J0324100*	OFS blanking plug assembly
H0J1236900**	External pressure testing fixture

*To be used in applications where the lowest gauge in the completion has been ordered with electrical feedthrough and requires to be blanked off.

**For applications where OFS seals require to be tested in the direction of pressure

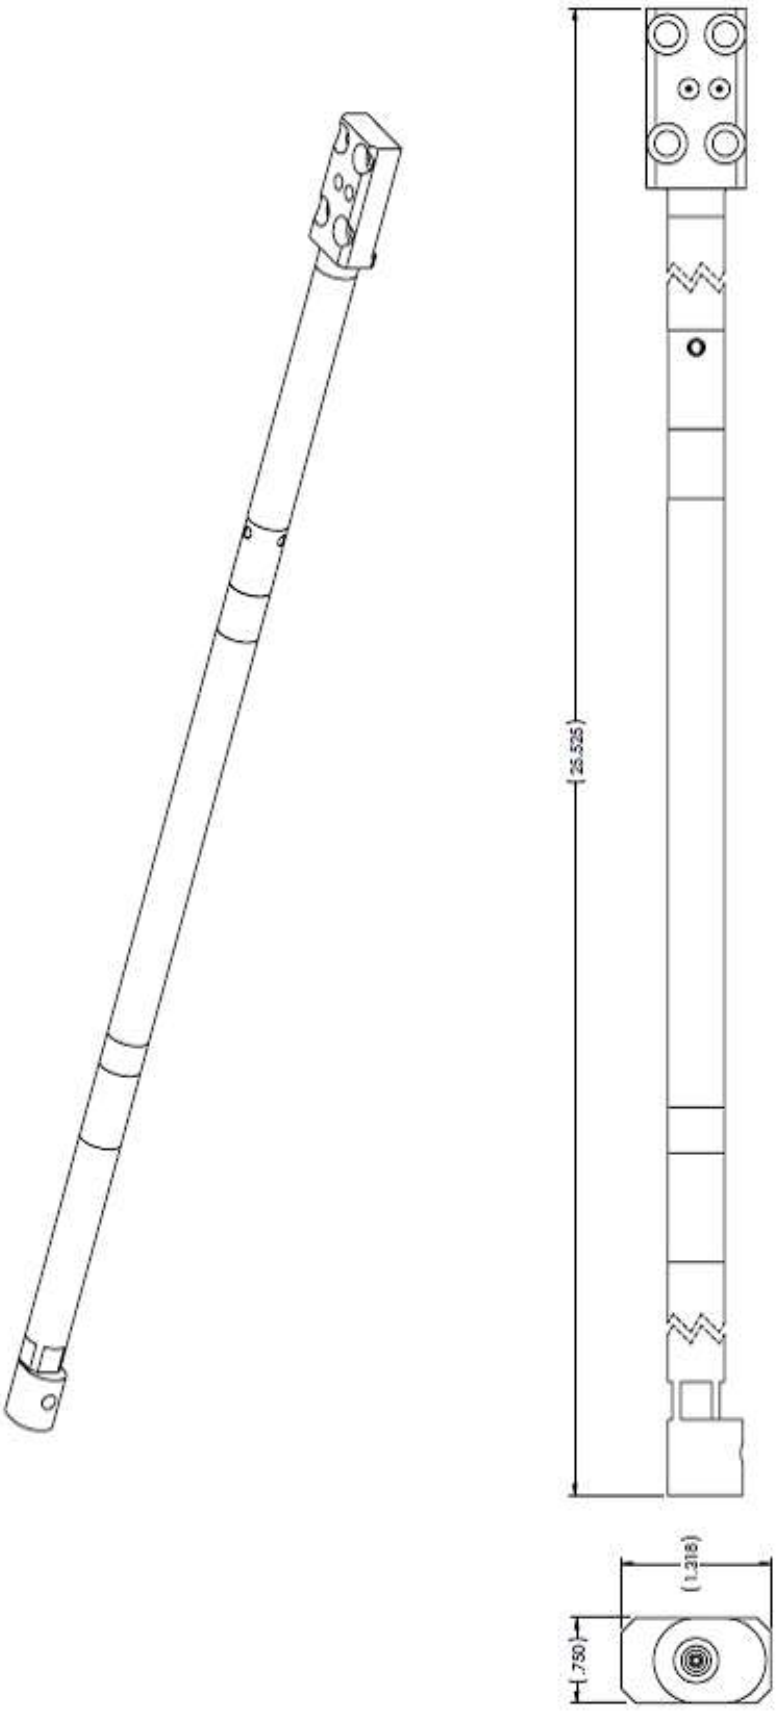
6 HSE&S

Read, understand and follow all Baker Hughes Company instructions and specifications in this unit while assembling, disassembling, maintaining or repairing this equipment. Failure to do so may result in property damage, serious injury or fatality.

7 Preservation of Product

For preservation of product requirements refer to the global procedure *for OFS Preservation of Product (QA-GLB-En-100042)* and *CWI Storage and Preservation Guidelines (AMO-GLB-En-101887)* located on Baker Hughes Operating System (BHOS).



Storage Recommendations

Adequate storage facilities must be established for equipment to prevent inadvertent damage due to moisture, humidity, vibration, shock and handling. Equipment will be appropriately protected during transport and handling.

SureSENS QPT ELITE Downhole Pressure Temperature Gauge

Figure 4: Assembly Drawing J06-526-00 (tubing with feedthrough)

9 Appendix

Hand Tools Required

- Encapsulation stripping tool
- 12-in. steel rule or dial calipers
- Tubing cutter
- Triangular file
- Large vise grips
- 3/16-in. through 5/16-in. coaxial cable stripper (IDEAL 45-165)
- 1/8-in. coaxial cable stripper (IDEAL 45-162)
- 12-20 AWG wire stripper
- DMC AF8 crimp tool
- Swaging tool (Material PGA-80-09000)
- 12-in. adjustable wrench
- Torque wrench ft.lb scale with interchangeable head (Snap-on QC2I75 or CDI 75MFIMHSS)
- Jam nut torque wrench head (BH Material H0J0531502 or Snap-on QJRXS16A)
- 5/8-in. wrench
- Torque wrench (in.lb scale)
- 3/16-in. hex socket bit

If deploying the external pressure testing fixture the following will be required:

- Clamp assembly (Material H0J1237000)
- Modified drive adapter (Material H0J1166900 or CDI TCQJRXS12A)
- 3/8-in. crows foot wench (Material 10601424 or Snap-on FRH120S) not required if using CDI TCQJRXS12A

Consumables Required

- P600 emery paper
- Silicone grease DC111
- TUNAP Tungrease CF-33 grease paste

Pressure Test Equipment Required

- Hand pump or HPU with transformer oil (Shell *DIALA* or equivalent)
- Chart recorder or pressure recording digital gauge
- High pressure lines with 1/4-in. autoclave high-pressure connections
- High-pressure T-piece
- High-pressure needle valve
- Pressure test adaptor (Material H0J0419300)

Volumetric Flow Meter

Sentinel LCT

Panametrics ultrasonic flowmeter for liquid custody transfer measurement

Benefits

- Extremely reliable and highly accurate flowmeter, designed specifically for custody transfer measurements.
- Viscosity independent. Measurement accuracy will not be affected by a change in viscosity or density.
- Fully welded construction with no moving parts. No filters or strainers required.
- Full bore design, zero pressure drop.
- Robust Path Configuration™ through extensive use of CFD (Computational Fluid Dynamics).
- Optionally built-in flow computer for API MPMS 11.1 corrections for temperature and pressure.

Applications

- Liquid custody transfer measurement
- Allocation measurement
- Pipeline leak detection
- Crude oil and refined products
- High temperature flow
- Cryogenic flow
- Any liquid flow needing high accuracy and precision

Panametrics
a Baker Hughes business

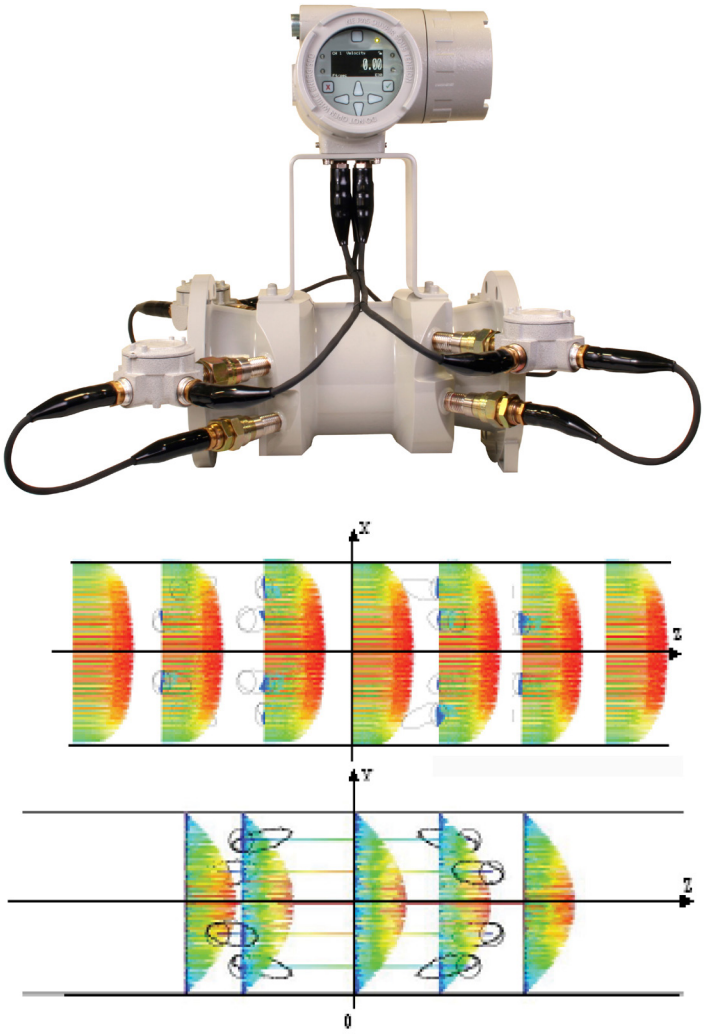
Custody transfer flow measurement from panametrics

Panametrics introduces Sentinel LCT, a new addition to our series of advanced ultrasonic flowmeters. Sentinel LCT demonstrates new levels of performance and accuracy, reacts to changes in flow rate with incredible speed and is based on proven technology. Sentinel LCT is designed specifically for the custody transfer measurement of crude oil and other liquid refined products and requirements. Please contact Panametrics for details.

It's all about reliability

The design philosophy behind Sentinel LCT was simple; build a flowmeter that combined absolute reliability with the highest accuracy. Using ultrasonic technology was the first choice; with no moving parts the meter will not suffer from any mechanical wear or tear. Using a fully welded construction without any gaskets or threaded connections was another choice; there is simply nothing in the meter's geometry that can change to allow th meter to drift.

Robust Path Configuration™



Before Sentinel LCT was ever tested on a calibration loop, the meter was already extensively tested in the virtual world. Computational Fluid Dynamics (CFD) was used to simulate different path configurations under different flow scenarios.

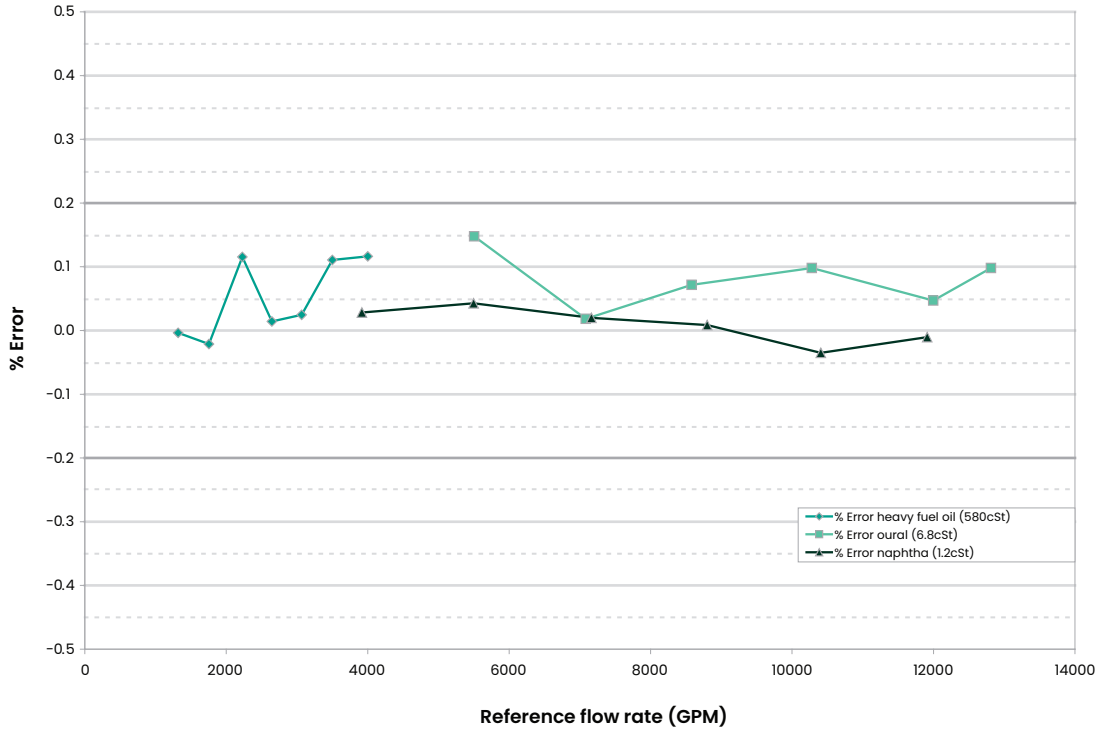
CFD allowed us to test different ultrasonic path configurations under a number of different flow scenarios, from laminar flows that are typically seen in very heavy crudes to highly turbulent flows that are seen in gasoline and LPG applications. Only after CFD simulation provided the optimal path configuration, was the Sentinel LCT tested in a calibration loop to prove the CFD results.

Testing on different viscosity oil products proved the CFD analysis to be right. Sentinel LCT easily met the targeted 0.15% accuracy.

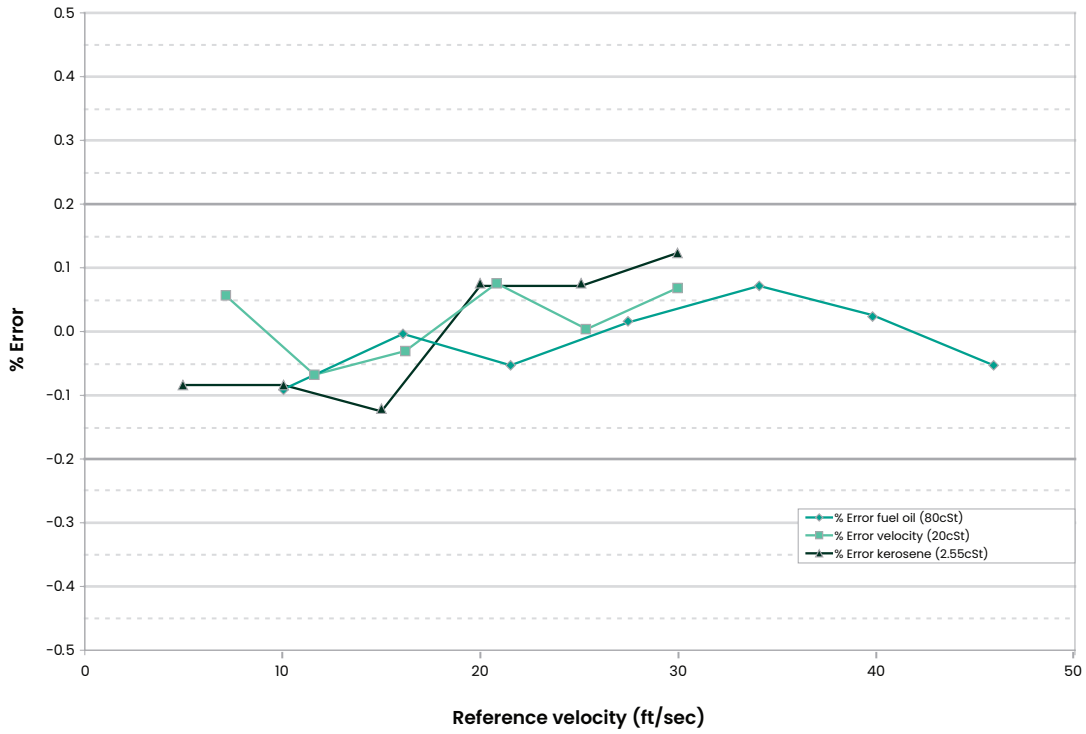
A true multi-viscosity flowmeter

Starting with a meter that already has minimal sensitivity to viscosity changes, Sentinel LCT uses a number of proprietary algorithms to even further reduce the viscosity effects. As a result, Sentinel LCT is a true multi-viscosity meter, meaning no prover run or change of settings is required when the viscosity changes. The meter stays within 0.15% accuracy over the whole range between minimum and maximum viscosity, using only one calibration curve.

CFD analysis of the ultrasonic port effects. The top graph shows the effect under turbulent flow, the bottom graph under laminar flow conditions. Also not the different flow profiles under these conditions.



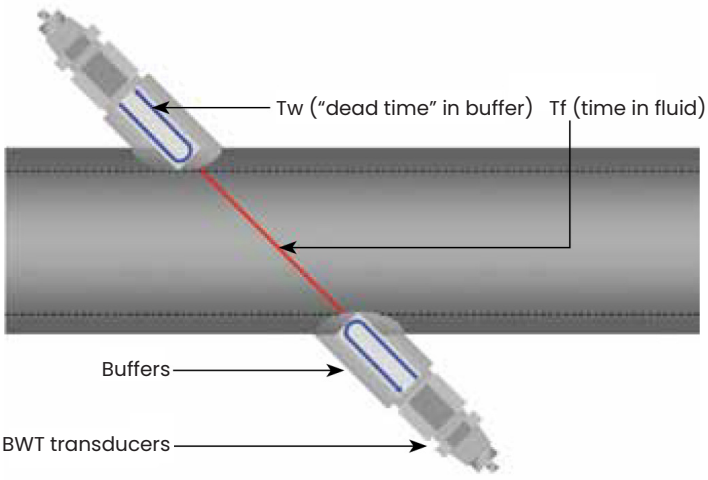
Maintenance free



Not only does the meter lack any mechanical parts that require maintenance, the meter also does not require any filter or strainers. Inspecting and replacing clogged filters is not required, simply because they are not there. Theoretically the meter does not even require any recalibrations; however, local legal requirements might require differently.

No pressure drop

Due to the unique ultrasonic path configuration, the flowmeter design does not have any diameter reductions. This means the design is completely full bore in the same diameter as your pipeline. As a result the pressure drop over the meter is simply equal to a section of pipe with the same length.



24” Sentinel LCT combined performance results: NMi witnessed results for OIML R117-1 certification at SPSE

Active Temperature Compensation™

Ultrasonic flowmeters use transit time to determine the liquid or gas flow in a pipeline. Measured transit time consists not only of the time the ultrasonic signal spends in a fluid, but also of a portion of "dead time," being the time that the electrical signal is converted into an acoustical signal and the time the acoustic signal travels inside the transducer. To allow for the utmost accuracy, Sentinel LCT uses pulse echo to actively measure the dead time. By sending a pulse and measuring its reflection, the dead time is measured in real time rather than using a preset value. As a result of this Panametrics invention, Sentinel LCT maintains custody transfer accuracy as process temperature conditions dynamically change.

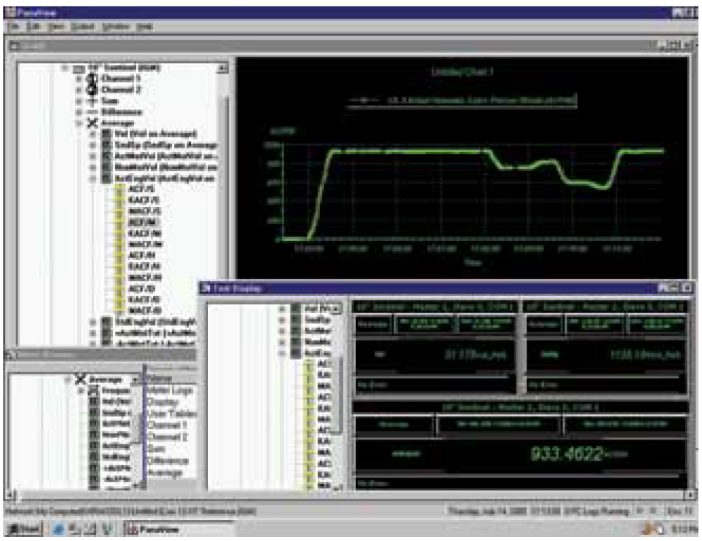
Built-in flow computer

Optionally the Sentinel SEN898 electronics have a built-in flow computer that allows for temperature, pressure and density corrections according to API MPMS 11.1. By connecting an external pressure, temperature and, if required, density measurement, all API corrections are done inside the SEN898 electronics, reducing the need for an external flow computer.

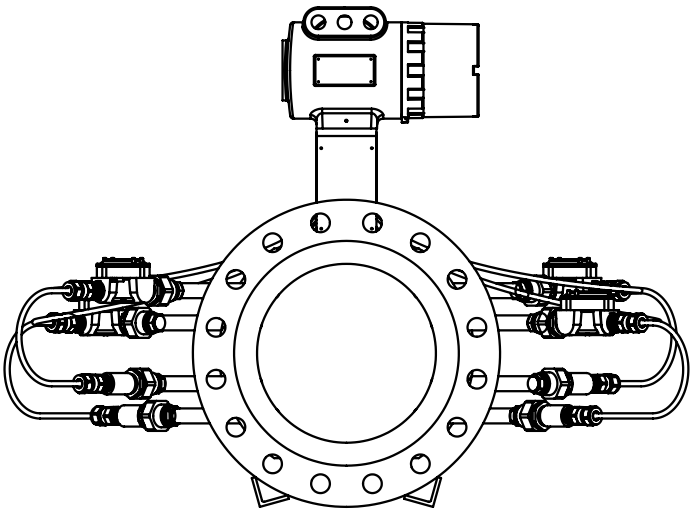
One-time calibration

The Sentinel LCT requires a single calibration event (multi-viscosity or water, depending on the application) to work over the entire user flow range without the need for frequent calibration checks or prover runs.

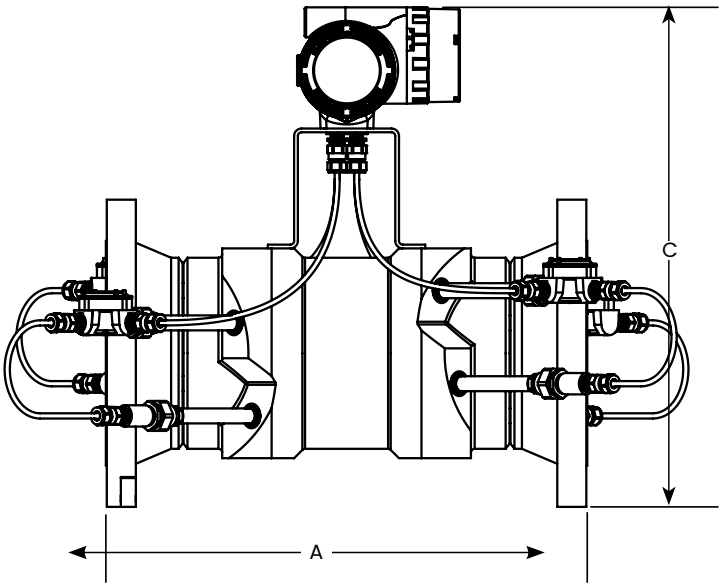
There is no need for recalibration when replacing sensors or electronics. NMI tested and certified that the Sentinel LCT maintains custody transfer accuracy and calibration integrity after component exchanges!



Advanced electronics



Sentinel LCT has advanced digital signal processors that pack significant power in a simple package. Several output options are standard. The electonics can be mounted on the flowcell section or up to 300 feet away. Cable connections can easily be accessed, even when the meter has been mounted to a wall. HART is standard on all meters. Local diagnostics can be done via magnetic contacts through the glass, or by using the USB connection and our PanaView™ software.



PanaView™ for diagnostics

PanaView software facilitates communication between a PC and the Sentinel LCT flowmeter. This software monitors the Sentinel flowmeter to provide a secure and comprehensive check on the meter configuration with a full audit trail. It also allows live flow readings and tracking of flow diagnostics.

APPENDIX D-III

MS USDW 1 & MS USDW 2 Drilling and Logging Procedures and Schematics

MS USDW 1
Drilling and Logging Procedure and Schematic

Minerva South USDW Well No. 001

MONITORING WELL DRILLING & LOGGING PROCEDURE

The following paragraphs discuss the drilling procedures to be implemented to construct the monitoring well to an approximate depth of 1,970 ft. The monitoring wells will be constructed in accordance with LAC Title 56 Chapter 3. Drilled is responsible for maintaining hole stability during all operations. Final acceptance is contingent on casing and screen being installed to correct depth as approved by owner.

Location Preparation

1. Survey and stake location as required to fit rig chosen to drill the well. Obtain ground level elevation.
2. Level and grade location as required. Prepare containment pit for solids returns when drilling the well.
3. Prior to mobilization, confirm that the office of conservation has received and responded to well installation notification as required in LAC43:VI.701.B.
4. Assure sufficient fresh water supply on site for drilling operations.
5. Mobilize at least one approved portable toilet to site.
6. Assure that rig inspection has been performed prior to rig moving to site.

Mobilization and Rig Up of Drilling Equipment

1. Move in drilling rig and associated equipment and rig up. Assure that drilling rig is leveled.
2. Check drill stem, stabilizers and drill bit inspection papers. Do not accept rig if there is any doubt about the condition of the rig or associated equipment. Confirm the number of tubulars on location.
3. Arrange for delivery of 4 1/2-inch, 3.3 lb/ft, fiberglass casing to location. Offload casing to pipe racks.

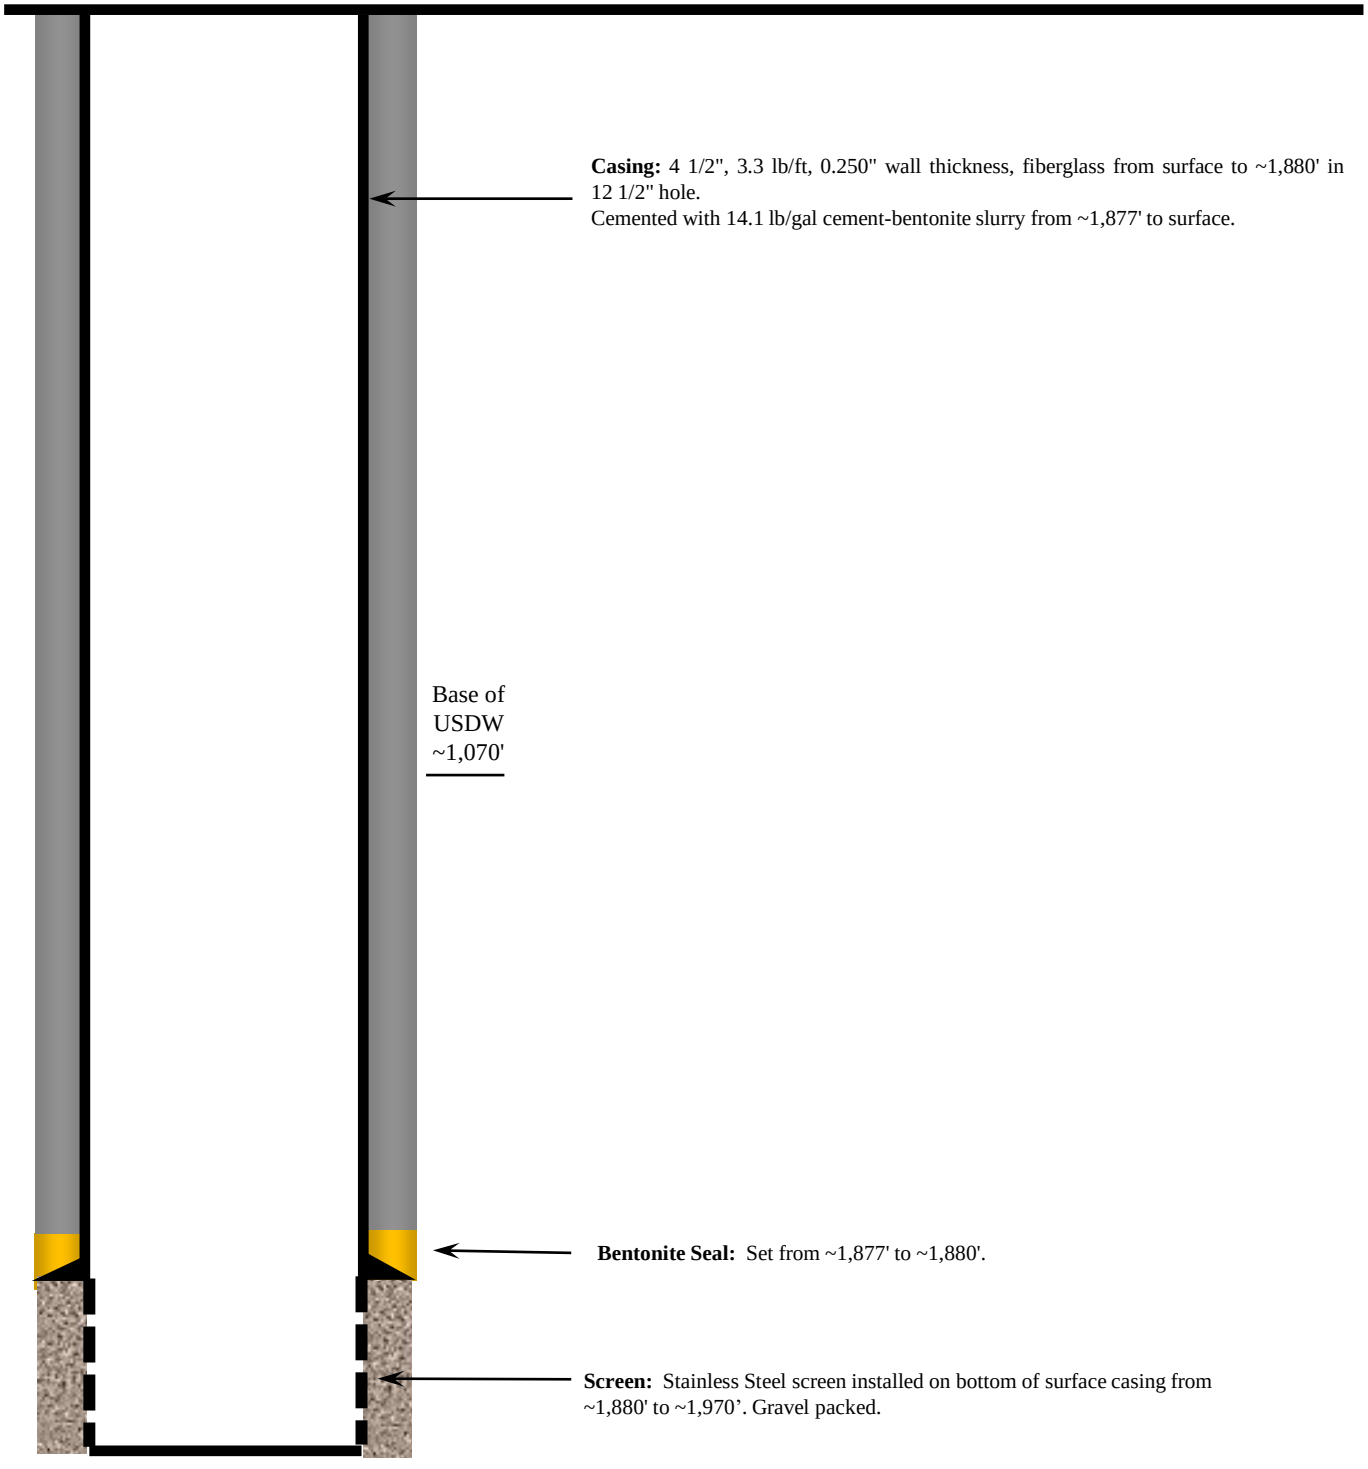
Surface Borehole and Surface Casing Installation

1. Pick up 12 1/2-inch drill bit with appropriate stabilized drilling assembly.
2. Rotary drill down to 40 ft.
3. Pull the drilling assembly out of the hole and install diverter. Rig up diverter flowline to containment pit for solids returns.
4. Run back in hole with 12 1/2-inch drilling assembly and rotary drill 12 1/2-inch borehole to approximately 1,970 ft at penetration rates of between 50 to 80 feet per hour to avoid loading the fluid returns with excessive cuttings. The hole should be

Copyright © 2024 by Terra Dynamics Incorporated

tested for plumbness and alignment should be exercised following the American Water Works Association Standards for Water Wells (AWWA A-100). Record depth and thickness of formations penetrated. Collect drill cuttings from each potential aquifer. Record any unusual occurrences such as loss circulation, cave ins, etc.

Note: In the event the unusual occurrence is observable evidence of naturally occurring methane gas, natural gas or similar sub-surface gas, such as bubbling drilling mud or gas venting at the well bore or other nearby surface location or feature, the contractor shall report such event verbally to the Environmental Division of the Office of Conservation within 24 hours per LAC56:III.323.C.4.



5. Pull drilling assembly out of the hole.
6. Run spontaneous potential, resistivity and natural gamma ray logs. Identify lowermost underground source of drinking water (USDW) and sand package below USDW.
7. Plug back borehole as needed to provide base for screen.
8. Pick up first joint of 4 1/2-inch, 3.3 lb/ft, fiberglass casing and install stainless steel screen.
9. Make up and run the remaining 4 1/2-inch, 3.3 lb/ft, fiberglass casing to approximately 1,970 ft (to place screened section across sand package) while making up joints to appropriate torque. Fill the casing every 5 joints with fresh water as needed while running into the well. Run centralizers and tremie pipe while making up and running the fiberglass casing.
10. Mobilize cementers to location. Rig up to water supply. Gravel pack screened section while pulling tremie pipe to top of screen. Mix bentonite plug and pump it down the hole through the tremie pipe to fill three feet in the annular space above the screen. Pull up above the bentonite plug. Mix 14.1 ppg cement-bentonite slurry and pump it down the hole through the tremie pipe. Slowly work the tremie pipe uphole until cement reaches the surface.
11. Wait on cement for at least 12 hours.
12. If cement fell back, top off annulus space as needed.
13. Construct a concrete slab at least four inches thick and extending at least 2.5 ft from the well in all directions at surface. The surface of the slab shall be sloped to drain away from the well.
14. Cut casing if needed to be at least one ft above ground and install protective cover or cap.

Rig Down and Demobilization

1. Clean up as needed and rig down drilling rig and associated equipment.
2. Release drilling rig and demobilize from location.

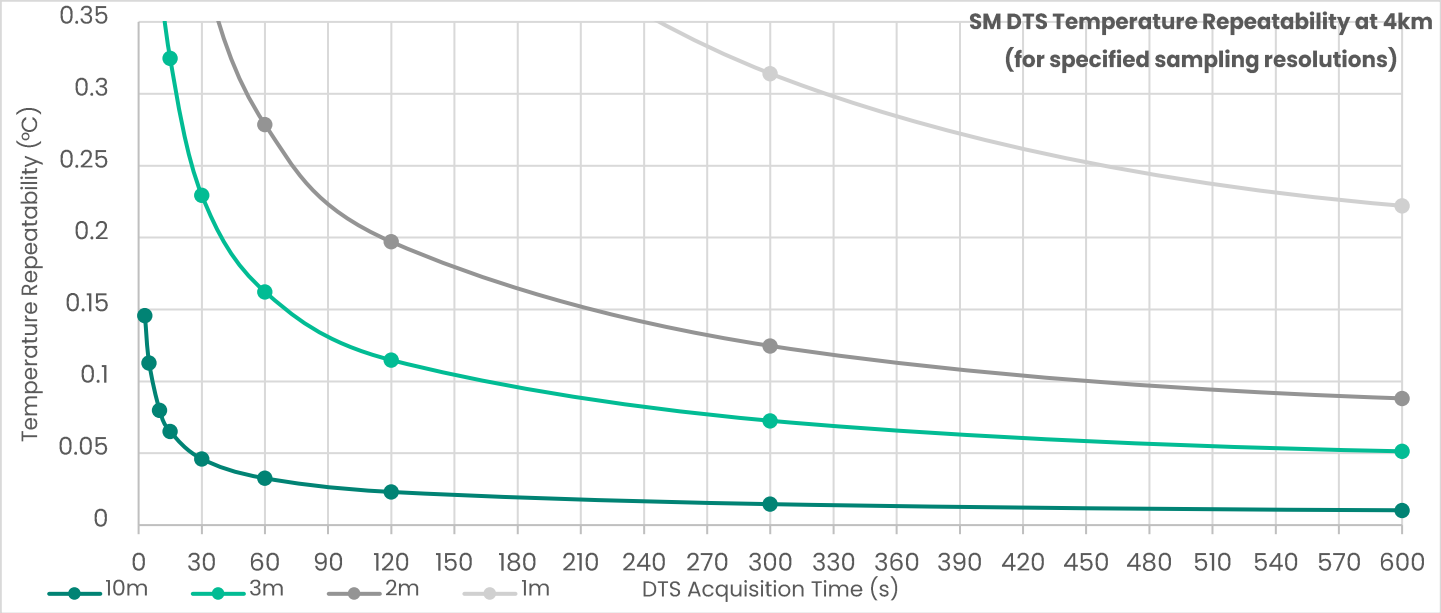
Mechanical Integrity Testing Tool

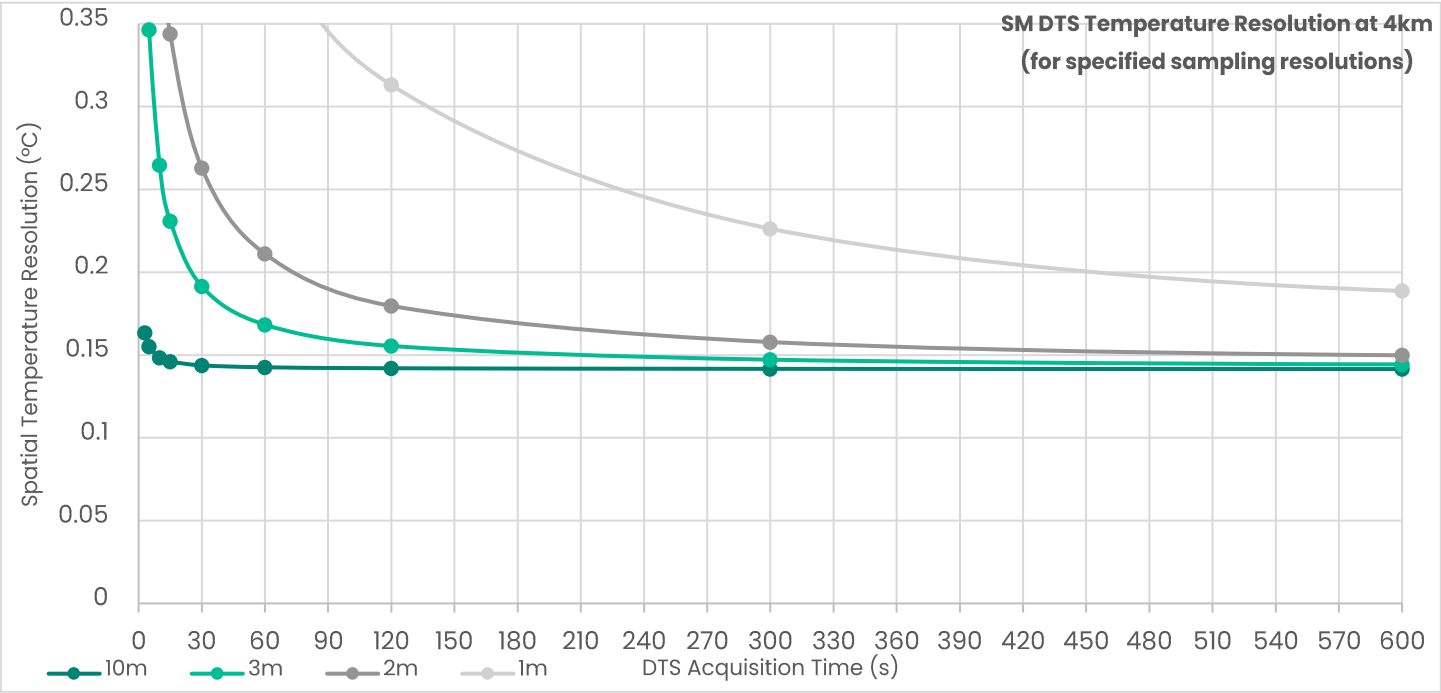
Specification Sheets

Distributed Temperature Sensing (DTS)

Baker Hughes



SureVIEW™ DTS Interrogator



The SureVIEW™ DTS fiber optic interrogator provides convenient multi-well performance monitoring with continuous, rapidly updating temperature profiles along the length of the completion. The interrogator is designed to provide highly accurate temperature data from a single SM fiber, which reduces cost by eliminating the need for dual-ended fibre configurations.

SureVIEW™ DTS Surface Interrogator Specifications	
Description	**Value**
Form Factor	19 in. Rack
Height	2U
Depth (in.)	19.8
Certifications	TUV (US, Can), CE
Public Software Interfaces	OPC/UA, Modbus
Maximum Distance Range (km)	20+
Minimum Spatial Resolution (m)	1.0
Minimum Sampling Interval (m)	0.33
Fastest Acquisition Rate (sec)	3.3
Number of Channels	8 or 16
Internal Data Storage Capability	250 GB
Fiber Types	9/125 µm SMF CoreBright™
Optical Connectors	Fiber Pigtails
Computer Interfaces	Ethernet, DPI, USB
Power Consumption (W)	100 W maximum

SureVIEW™ DTS Surface Interrogator Specifications	
Description	**Value**
Voltage Input	22-27 VDC
Differential Attenuation Compensation	Yes
Fiber Configuration	Single-Ended or J-Type
Absolute Temperature Accuracy (°C)	±2 (worst-case, rapid cycling over full operating range)
Operating temperature (°C)	0 to 40
Storage temperature (°C)	-40 to 80
Operating relative humidity (%)	5 to 95
Sensing temperature Range (°C)	0 to 300

Call your local Baker Hughes representative today to learn more about how SureVIEW monitoring systems can reliably enhance your production operations.

Noise Log

Sondex™
a Baker Hughes business

Noise Tool (NTO)

Detects liquid or gas movement sounds in leaks, channels, or perforations

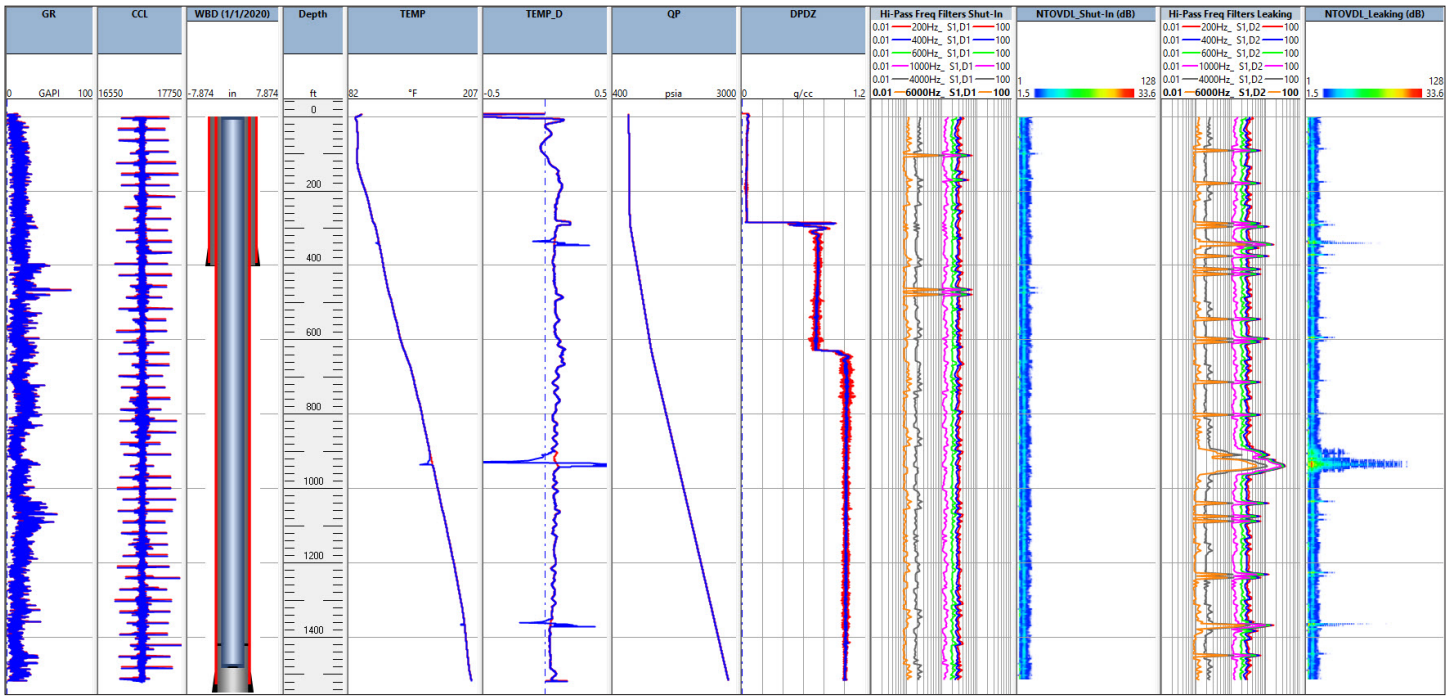
Application

- Evaluate flow profiles
- Locate channels behind a well case
- Locate gas-liquid interfaces
- Locate leaks in a well case
- Locate gas entries

Features

- Several NTO can be combined in one string
- Real time fast Fourier Transform (FFT) spectrum monitor
- Color variable-density log (VDL) style spectral log
- Road noise filter
- Configurable sampling modes (average, minimum, and maximum)
- Combinable with all Ultrawire tools
- No cable attenuation
- Configurable frequency cuts
- SRO or memory operation quantitative measurement

A leaking well can damage the environment and result in lost production. The **Noise Tool (NTO)** houses a sensitive hydrophone that is highly effective in the detection of flow inside and outside the cased well. The electronics digitize the noise downhole and sends a frequency spectrum to the surface to be recorded. Both the frequency spectrum and six high-pass frequency cuts are displayed on a log, providing a quantitative measurement of the downhole noise.



The NTO can be combined with other **Sondex Wireline tools** and logs data in both memory or surface readout tool strings. Consequently, any cased-hole logging intervention, such as production logging, cement evaluation, or pipe inspection, becomes an opportunity to verify the integrity of downhole components at minimal additional cost.

Multiple NTO can be combined within a single toolstring, thereby making it possible to pinpoint the depth of any particular noise source effectively and efficiently. The NTO is typically run in combination with a casing collar locator and temperature tool as well as any other **Sondex Ultrawire tool** such as Gamma ray, pressure, cement bond, calliper, metal thickness, or production log.

Specifications

	FlexSand LS
Temperazture rating	350°F (177°C)
Pressure rating	20,000 psi (138 MPa)
Tool diameter	$1^{11}/_{16}$ in. OD (43 mm)
Tool length	24 in. (609.6 mm)
Tool weight	10 lb (4.53 kg)
Frequency range	100 Hz to 12,700 Hz
Amplifier gain	22.4 to 67.8 dB (or x13 to x2455)
Resolution	16 bit
Dynamic range	72 dB
Data reading rate	0.5 sec
Sample length	10 ms
Sample rate	25.6 kHz
Number of spectral channels	128

Combined plot of NTO data with other measurements like pressure and temperature. Comparison of shut-in and leaking surveys allow identification of leak location

RESERVOIR PERFORMANCE MONITOR (RPM)

Advancing Reservoir Performance
Formation evaluation and reservoir monitoring

TIER 1

COMPREHENSIVE RESERVOIR EVALUATION AND MANAGEMENT

The Reservoir Performance Monitor (RPM™) platform is an advanced, slimhole, multifunction, pulsed neutron reservoir monitoring instrument. Its instrumentation combines multiple nuclear measurements in one system with industry-leading accuracy and precision. Carbon/oxygen (C/O) and pulsed neutron capture (PNC) measurements acquired with the RPM tool provide water saturation and three-phase holdup determination, while oxygen activation measurements allow detection of water flow and channels.

RPM services address a broad scope of reservoir evaluation and management applications, including reservoir saturation and produced fluids monitoring, formation evaluation, production profiling, workover and well abandonment evaluation, borehole diagnostics, location of bypassed oil, gas detection and quantification, and identification of water production.

The RPM instrument employs three high-resolution gammaray detectors arrayed above an efficient and reliable neutron generator. State-of-the-art detector electronics measure both the arrival time and energy of detected gamma rays. The generator is pulsed at distinct frequencies, and the data acquisition system operates in various timing modes to obtain the different logging measurements. The system hardware is combinable with other production logging instruments; and it is constructed in short, modular sections to facilitate shipping and handling.

ACCURACY IS PARAMOUNT

The accuracy of the RPM service has been ensured by extensive physical characterization in Baker Hughes' Houston Technology Center. The tool's measurements have also been enhanced by 3-D and Monte Carlo modeling to provide accurate response in a wide range of borehole, casing, formation, and fluid conditions; and Baker Hughes' unique Dynamic Response Generator™ feature delivers accuracy and confidence in any borehole geometry.

Unique downhole conditions can be modeled to ensure that analysis of the reservoir is the most accurate available. And extensive pre-job planning tools are available for design of a data acquisition program that optimizes the final answers delivered by the service.

EFFICIENCY IS DESIGNED IN

Flexibility and operating efficiency make the RPM tool a complete multimode, multisensor, solution-based system. All operating modes are selectable by surface commands.

The RPM instrument can be run in combination with conventional production logging sensors to provide a complete picture of a well's production and reserves in a single trip. It can also be combined with Baker Hughes' unique Multi-Capacitance Flow Meter (MCFM™) instrument in the POLARIS™ system for evaluation of highly deviated wells.

WHY THE RPM TOOL WORKS SO WELL

The RPM instrument uses high-energy neutrons to measure both the inelastic and capture gamma rays.

The inelastic gamma rays, produced by fast neutron collisions during the accelerator pulse, are used for carbon/oxygen measurement to determine the formation water saturation in formations with fresh or unknown connate water salinity.

The capture gamma rays, generated by the absorption of slow or "thermal" neutrons after the pulse, are used to measure formation water saturation in formations with saline connate water. The sensitivity of the capture process to salinity produces a log response similar to a conductivity measurement, where the measured thermal neutron absorption cross section (∑) is used to determine water saturation.

Baker Hughes

RESERVOIR PERFORMANCE MONITOR (RPM)

TIER 1

APPLICATIONS AND SOLUTIONS

FORMATION EVALUATION

- Cased hole water and gas saturation measurements
  - Through casing (with through-tubing deployment capability)
  - When openhole logs are unavailable or uneconomical
- Quantification of total hydrocarbons in medium- to high-salinity conditions
- Quantification of liquid hydrocarbons in low- and mixed-salinity conditions
- Identification and quantification of gas, independent of salinity
- Evaluation of porosity
- Identification of mineralogy

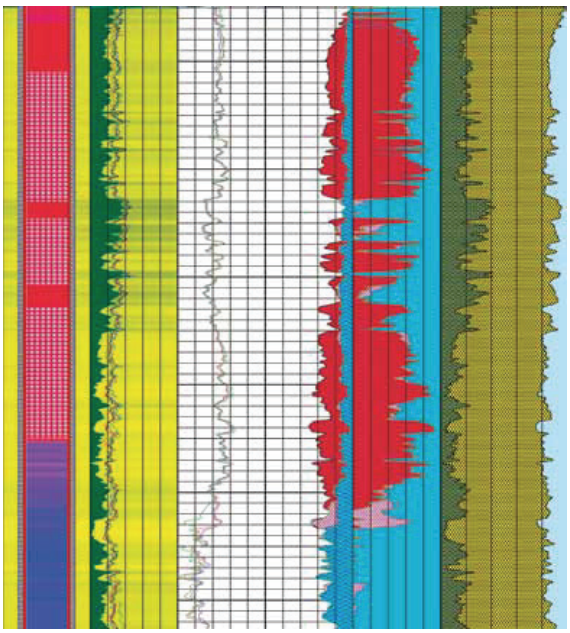
RESERVOIR MONITORING AND MANAGEMENT

- Monitoring fluid contacts
  - Time-lapse fluid monitoring
  - Gas/oil/water contact levels
  - Production and reservoir depletion
  - Identification of bypassed hydrocarbons
- Reservoir management base logs

BOREHOLE DIAGNOSTICS

- Identification of water channeling and casing leaks
- Production/injection profiling in multiple-string completions
- Multiphase borehole fluid holdup determination

WORKOVER APPLICATIONS



- Location of bypassed hydrocarbons, independent of water salinities
- Evaluation of stimulation operations
- Log-inject-log surveys for determining irreducible hydrocarbons
- Production/injection profiling

The RPM instrument employs three high-resolution gamma-ray detectors arrayed above an efficient and reliable neutron generator.

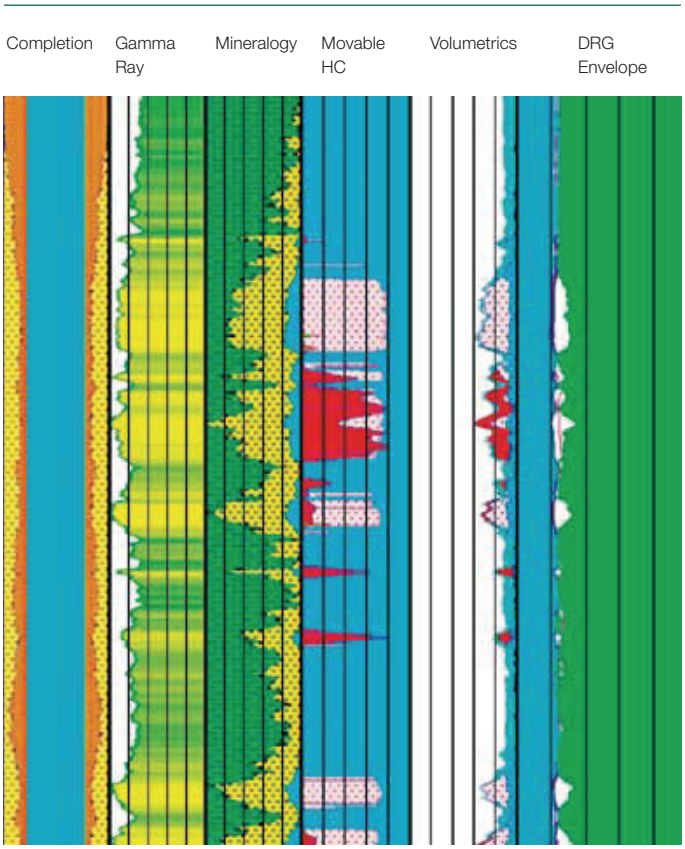
PULSED NEUTRON CAPTURE

In the Pulsed Neutron Capture (PNC) logging mode, the detectors record the arrival time of the gamma rays, from which the formation ∑ is determined. Time spectra from short-spaced and long-spaced detectors can be processed individually to provide traditional ∑ information. The multiple spectra are processed simultaneously to correct for borehole and diffusion effects, producing a real-time corrected formation ∑ measurement. Multiple additional measurements are provided to measure formation porosity, shale volume, and borehole fluid changes, as well as to identify formation gas.

Advanced interpretation of PNC data is available through Baker Hughes' GEOScience centers using the SEARCH™ analysis program. The identification of gas zones and the measurement of formation gas saturation is performed using the PNC mode. In this application, Baker Hughes combines special instrumentation, response characterization, and an interpretation algorithm to produce a state-of-the-art gas measurement.

Apparent measurements from near and far detectors are combined to produce a real-time corrected formation ∑.

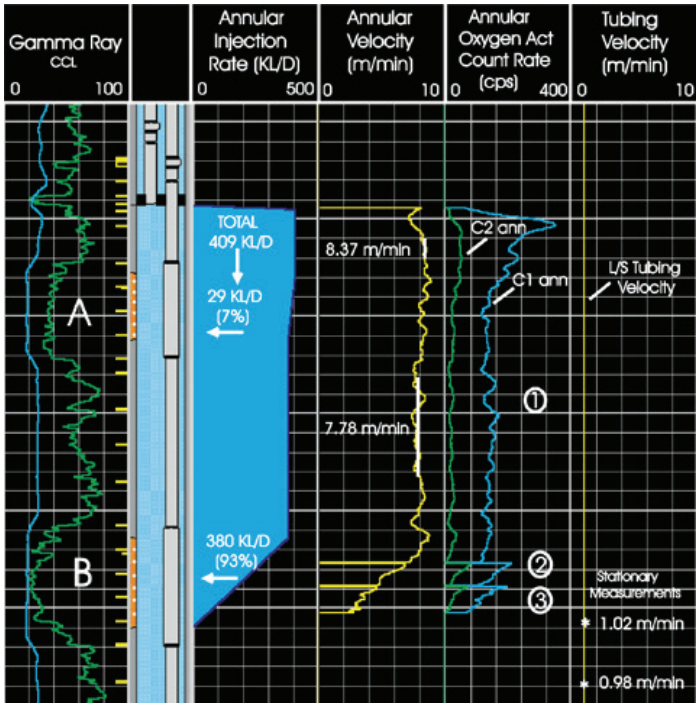
Baker Hughes



RESERVOIR PERFORMANCE MONITOR (RPM)

TIER 1

CARBON/OXYGEN LOGGING



When formation waters are fresh, brackish, or of mixed or unknown salinity, the RPM-C/O acquisition mode is used to detect hydrocarbons. In this mode, direct measurements of the oxygen and carbon content of the reservoir are made, allowing differentiation of hydrocarbon zones from water-bearing zones.

Since chlorine has virtually no inelastic reaction cross section, the C/O measurement can be used to determine formation water saturation independent of salinity.

Interpretation of basic C/O data for monitoring hydrocarbon depletion of a sandstone reservoir.

FOUR MODES FOR OPERATING VERSATILITY

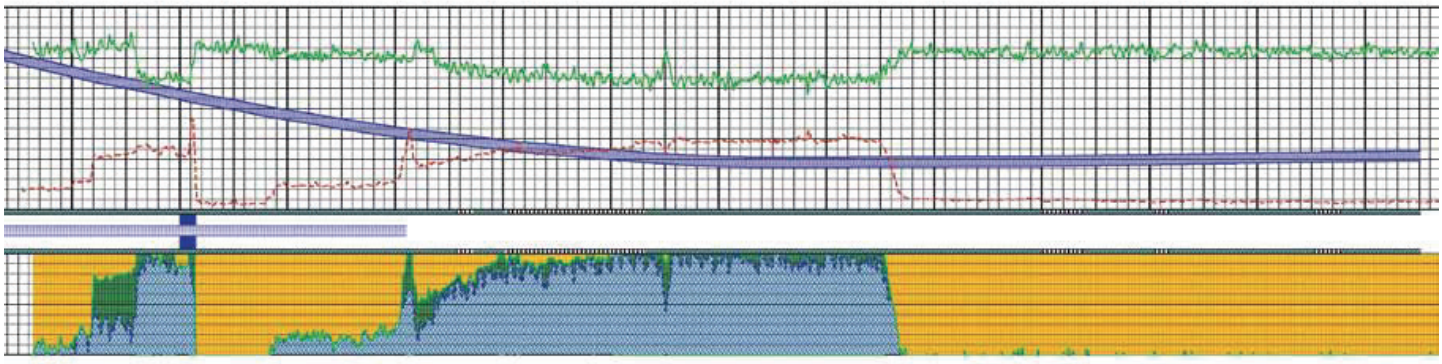
AFL volumetric analysis in a dual-string injection well determined that 7% of the injected fluids were entering zone A and 93% were going into zone B.

WATER FLOW LOGGING

The RPM Annular Flow Log (AFL™) and Hydrolog™ measurements use the principle of oxygen activation to measure water flow. In this application, oxygen is made artificially and temporarily radioactive through the neutronexchange reaction, allowing it to be used as a short-lived tracer. Detection of the movement of the activated oxygen can determine water velocity. These measurements provide a powerful diagnostic tool to identify movement inside the casing, outside the casing, or in the tubing-casing annulus. The measurement techniques allow detection of water movement from 2 to 500 feet per minute in simple and complex completions.

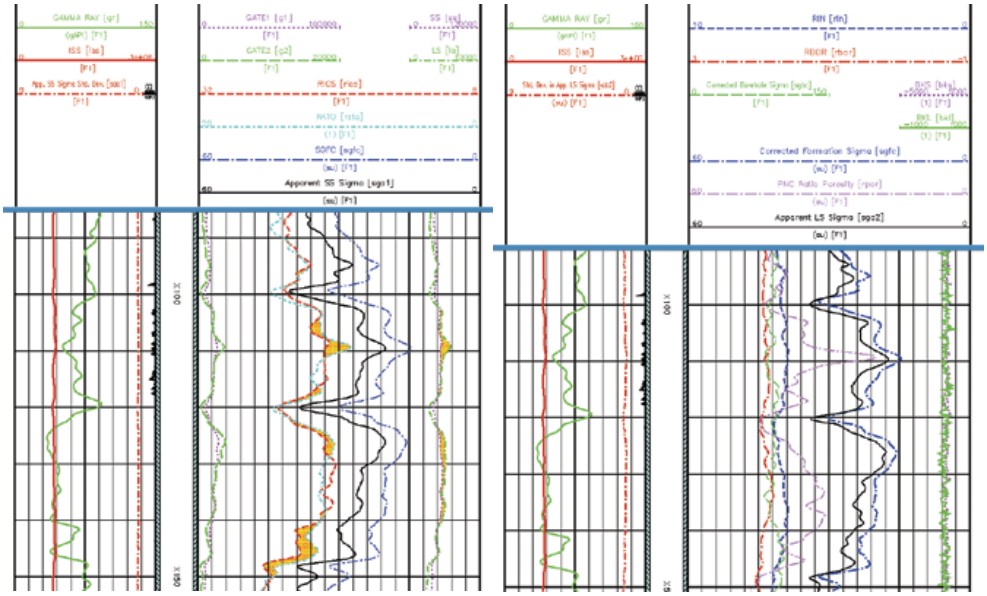
Baker Hughes

RESERVOIR PERFORMANCE MONITOR (RPM)



TIER 1

LOG YOUR MOST HOSTILE WELLS



The RPM-C instrument can provide accurate data in wells in which other pulsed neutron tools cannot even survive. It has industry-best standard environmental specifications of 350°F (177°C) and 20,000 psi (138 MPa). Specially modified hardware enables reliable service at temperatures to 500°F (260°C) and pressures to 30,000 psi (207 MPa).

HOLDUP IMAGING

The RPM Pulsed Neutron Holdup Imager (PNHI™) logging mode was designed for measurement of holdups of gas, oil, and water in horizontal boreholes. The PNHI measurement produces a continuous image of the borehole contents, independent of flow regime and unaffected by gravity segregation of the produced fluids.

The PNHI log can determine gas, oil, and water holdups in horizontal boreholes.

Although RPM-PNC data acquisition and processing provide analysis results and statistics that are superior to conventional PDK-100 measurements, the RPM-PNC log display and PDK-100 presentation are similar. In time-lapse studies, an emulation of the PDK-100 curve can be provided with RPM-PNC processing for easy comparison of their measurements.

BUILD ON THE DATA YOU ALREADY HAVE

RPM data can be matched with previous-generation PDK-100™ measurements for easy comparison in mature fields. The RPM service provides real-time emulation of PDK-100 measurements for comparison with historical logs. For remedial work and timelapse monitoring, RPM data can be overlaid with existing log measurements in real time, allowing rapid workover planning.

An advanced feature of the RPM service allows real-time computation of “intrinsic” ∑. Innovative data analysis techniques provide a ∑ measurement that is corrected for borehole and diffusion effects, without prior knowledge of borehole salinity.

OUR EXPERIENCE AT YOUR SERVICE

Expert support at the wellsite and from the Baker Hughes GEOScience Center provide the foundation for superior reservoir surveillance solutions.

Since inception, Tier 1 has provided cased-hole logging services. When required, we work with technology leaders that provide specific logging solutions. The RPM from Baker Hughes is an example of how Tier 1 will provide the best in service quality while deploying logging equipment supported by the experts of the technology.

WELL INTEGRITY: PIPE EVALUATION

High-Resolution Vertilog (HRVRT) service

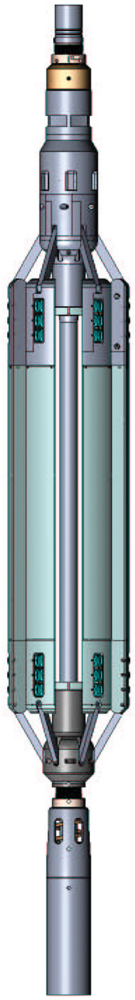
Evaluate pipe integrity with the fastest and most precise tool in the market

Applications

- Identify internal versus external corrosion problems
- Locate holes, corrosion, depth of penetration, and other defects
- Determine the effectiveness of cathodic protection and corrosion inhibitors
- Discriminate between actual corrosion and well completion equipment

Features and benefits

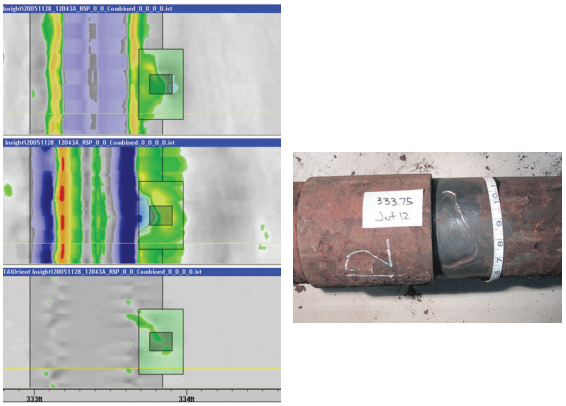
- Multiaxial sensors with next-generation multiaxis data technology
  - Offer improved defect descriptions with greater accuracy and reliability
  - Allow increased circumferential and axial resolution
- Dynamic range of applications in a variety of downhole conditions
  - Offers greater flexibility in logging below casing
  - Enables negotiation around casing patches and other hardware
  - Eliminates unnecessary remediation work and reduces unplanned production outages
- Deployable on wireline or **TeleCoil™ intelligent coiled tubing**
  - Provides flexibility for reaching optimal performance



The **High-Resolution Vertilog™ (HRVRT™) service** provides the industry's most precise pipe integrity and corrosion evaluation, accurately characterizing casing and tubing strength. The service eliminates unnecessary remediation work and reduces unplanned production outages.

This service also provides flexible and efficient data acquisition, reducing operating time while improving data accuracy and operational safety. In conventional magnetic flux-leakage (MFL) tools, the flux leakage sensors are coils; however, in the Sondex high-resolution tool, the coil is replaced by multiple "hall effect" sensors. The HRVRT service uses MFL measurements to identify and quantify internal and external corrosion defects.

The overlapping arrays of the multiaxial sensors, flux-leakage sensors, and discriminator sensors offer full circumferential inspection of the tubing or casing string. This process differentiates between metal-loss (corrosion) and metal-gain (hardware) features, and distinguishes between general corrosion and isolated pitting. The service provides tubular burst-and-collapse strengths based on customer-defined criteria, facilitating consistent and rapid evaluation of the well's integrity.



The HRVRT service provides a quantifiable defect description with an increased accuracy for length, width, and depth determination. This data is accurate for input into burst pressure calculations.

The HRVRT data acquisition is independent of logging speed. This allows it to better characterize defects in the well (especially near the wellhead), eliminate unnecessary remediation work, and reduce unplanned production outages.

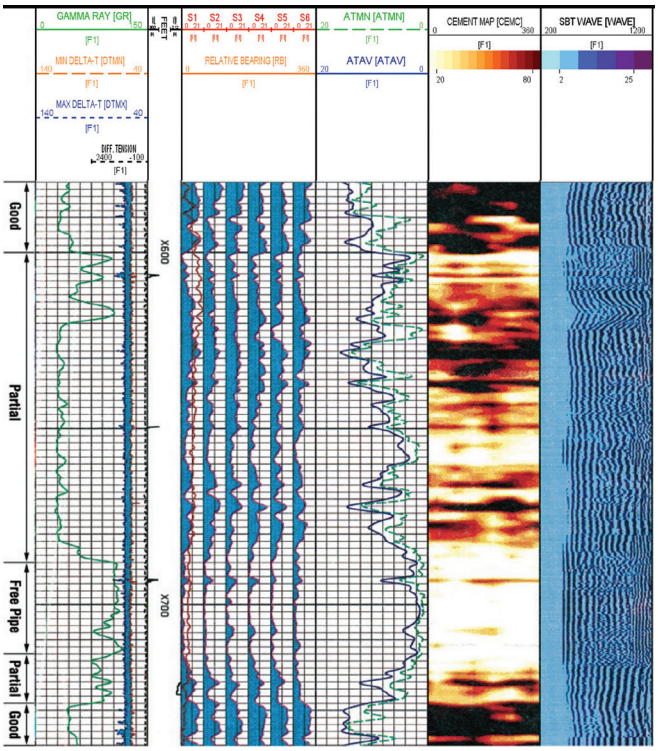
SEGMENTED BOND TOOL (SBT)

WELL INTEGRITY EVALUATION SERVICE



Confirm hydraulic isolation and avoid remedial work by evaluating cement bond integrity.

The Baker Hughes Segmented Bond Tool (SBT™) well integrity evaluation service quantitatively measures the cement bond integrity in six angular segments around the casing, delivering the information needed to confirm hydraulic isolation and determining whether remedial work is required before any completions are attempted. The SBT service operates at the ultrasonic frequency range, and quantitatively measures the cement bond integrity in six angular segments around the casing to ensure a strong hydraulic seal in these locations, thus improving productivity and well life span. The service can find and define channels in the cement annulus, enabling the operator to determine next steps. Conversely, the SBT service can reliably find zones of uniform bonding within a few feet of casing. Under conditions where a short-bonded interval produces an adequate hydraulic seal, squeeze jobs can be avoided.

The SBT service offers significant operating advantages over conventional and pulse-echo tools due to its insensitivity to heavy or gas-cut borehole fluids, dense muds, emulsions, fast formations, temperature and pressure variations, and moderate tool eccentering. The service can evaluate cement in heavyweight casings up to 1-in. thick.

For ease of interpretation, SBT measurements are displayed in two log presentations. Both presentations are available in the logging mode, as the SBT data are acquired, processed, and plotted in real time. The secondary presentation consists of six continuous segmented arrays, a variable-attenuation cement map, and a tool-orientation trace overlay—a field deliverable that does not require engineer interaction. It also provides a 5-ft-spaced variable-density log measurement, used to qualitatively understand the bonding between cement and the formation.

The SBT™ Beyond service enables the SBT service to extend the maximum casing size from 16 in. to 24 in., thus offering a tool covering the widest casing size range in the cement evaluation segment. The SBT Beyond service is capable of evaluating cement behind casing sizes larger than 133/8 in., which is unique in the industry. Combined with the benefit of this wide casing thickness range of the SBT service (up to 1-in. thickness), the SBT Beyond service addresses challenges in segments where pulse-echo devices cannot perform.

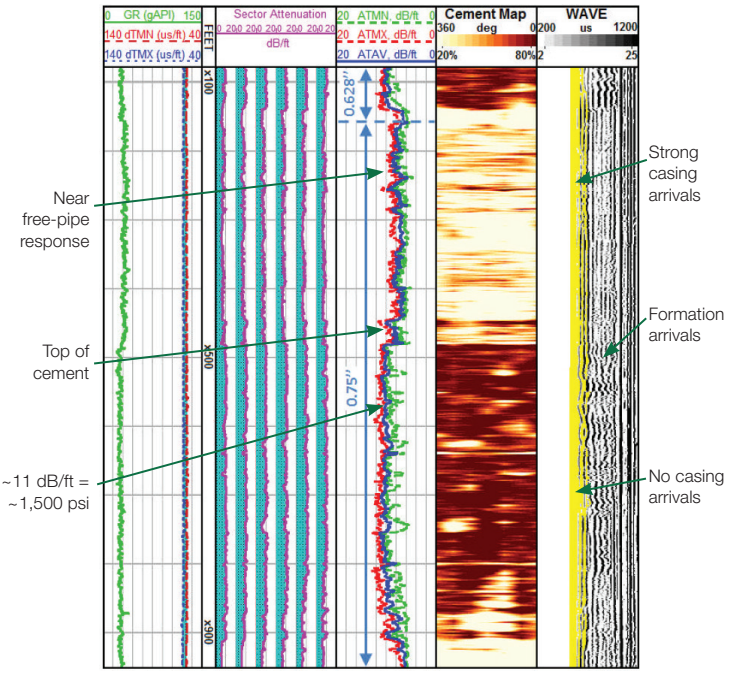
The field deliverable is a real-time, non-processed log that is not dependent on the logging engineer's input.

For more information on how the SBT service can help you determine if remedial work is required before completions are attempted, contact your Baker Hughes representative today or visit **bakerhughes.com/SBT**.

SEGMENTED BOND TOOL (SBT)

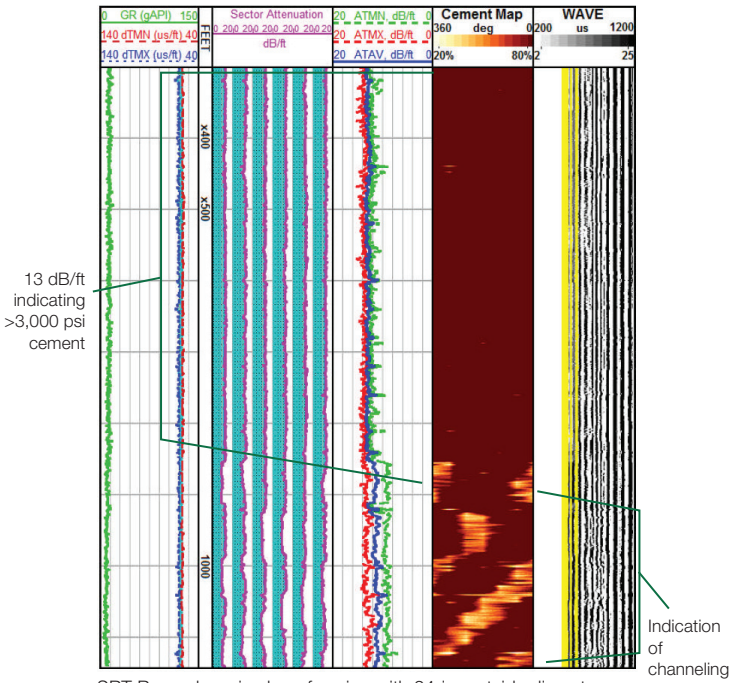
WELL INTEGRITY EVALUATION SERVICE

TIER 1 ENERGY SOLUTIONS | BAKER HUGHES a GE company



FEATURES & BENEFITS

- Pad-mounted
  - Identifies intervals of uniform bonding and detects cement channels or voids
  - Identifies channeling and poor cement bond sections to reduce risk
  - Reduces analysis time, using a 360° easy-to-interpret cement map
  - Provides accurate measurement in any type of formation condition, up to 1-in.-thick casing
  - Provides accurate measurement, even in fast formations, heavy mud, and thick wall casing
  - Evaluates multiple-size casing strings in one logging pass
- Insensitive to moderate eccentering
  - Enables deployment in the most challenging scenarios
- Fully compensated measurement
  - Unaffected by varying wellbore fluid conditions, pressure, and temperature
- Casing range from 4.5 to 24 in.
  - Provides the widest casing range coverage in the industry



APPLICATIONS

- Provides quantitative analysis of cement bond to the casing around the borehole
- Provides qualitative analysis of cement bond with the formation

Length	32.1 ft.	
Diameter	3.38 in.	
Pressure rating	20,000 psi	
Temperature	350°F	177°C
Weight	481 lb.

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY
REGION 5 -- UNDERGROUND INJECTION CONTROL (UIC) SECTION
REGIONAL GUIDANCE #5

DETERMINATION OF THE MECHANICAL INTEGRITY
OF INJECTION WELLS

Revised February, 2008

1 ISSUE

Demonstrations of mechanical integrity (MI) are the most common means of demonstrating that there is no movement of fluids into or between underground sources of drinking water (USDWs) associated with injection wells. Although relatively simple in theory, MI tests (MITs) must be conducted so that their validity as well as their outcome is evident. The Underground Injection Control (UIC) Branch of the Water Division in Region 5, United States Environmental Protection Agency (USEPA), as the authority in matters of MI in Region 5, should establish guidelines which will assist operators and regulators of injection wells in Region 5 subject to demonstrations of MI to conduct those demonstrations such that the results will be useful.

2 PURPOSE OF GUIDANCE

The guidelines were developed by the UIC Branch of Region 5 USEPA, to assist owner/operators of injection wells in Region 5 to demonstrate MI. Procedures varying from these guidelines may be accepted if first approved by the Director of the USEPA.

Pursuant to 40 C.F.R. &sect 146.8(a) "an injection well has mechanical integrity if: (1) there is no significant leak in the casing, tubing, or packer; and (2) there is no significant fluid movement into an USDW through vertical channels adjacent to the injection well bore". The absence of significant leaks is demonstrated through the use of tests which have been approved for that purpose by the Administrator (MI tests). The methods presently accepted for establishing MI pursuant to 40 C.F.R. &sect 146.8(a)(1) [part 1] of MI for wells operating in states in which the UIC Branch implements the UIC regulations, include: 1) the standard annulus pressure test (SAPT), 2) the standard annulus monitoring test (SAMT), 3) the radioactive tracer survey (RTS), and for certain Class III wells: the water-brine interface test (W-BIT. Other methods, including the Ada pressure test(AT) and the cementing pressure/single point resistivity test, are approved for national use under certain circumstances, but are not used in Region 5. In addition, the dual completion monitoring test (DCMT) is used by a few wells in Michigan and Indiana although interim approval has expired. The procedures for this test are under review. Accepted methods for demonstrating MI pursuant to 40 C.F.R. &sect 146.8(a)(2) [part 2] include: 1) the results of a temperature log, 2) noise log, 3) oxygen activation log, 4) the re.sults of a radioactive tracer survey (RTS) (when the injection zone is separated from the lowermost USDW by a single confining layer), or 5) for all Class II wells and for Class III wells in which the casing precludes the use of logging techniques, cementing records demonstrating the presence of adequate cementto prevent fluid migration into USDWs pursuant to 40 C.F.R. &sect 146.8(c)(2) and (c)(3) respectively. Demonstrations of both part 1 and part 2 of MI must be made before injection can be authorized.

The procedures which are recommended in the attachments to this document will, in most cases, result in development of valid data which Region 5 will be able to interpret with confidence. Deviations from these procedures may result in anomalies which will complicate or even invalidate test results. If the recommended test results do not result in definitive information, any anomalies noted should be investigated immediately, including re-doing the tests. Results which provide demonstrations of MI are the purpose of this guidance, but adherence to guidance may not ensure development of acceptable results in all cases. In such cases, mere adherence to guidance does not absolve the operator from the requirement to demonstrate MI. In cases in which there is doubt about the certainty of outcomes,

reference to and comparison with previous tests can often be used to clarify the test results. In this vein, comparison of tests through time, especially the comparison of temperature and radioactive tracer logs can make interpretation easier and make progressive change apparent. In all cases, operators should submit proposed testing procedures to the UIC Branch's Direct Implementation (DI) Section for approval before the testing is done. This can prevent misunderstandings and possible retesting.

3 DISCUSSION

3.1 Mechanical Integrity Pursuant to 40 C.F.R. &sect 146.8(a)(1)

There are a limited number of means by which part 1 of MI (the absence of significant leaks in tubing, casing, and packer) may be demonstrated. Therefore, little discussion of the relative merits of the various tests is necessary.

3.1.1 The Standard Annulus Pressure Test (SAPT)
The SAPT is the most common means used to demonstrate part 1 of MI. This test is based on the principle that a pressure applied to fluids filling a sealed vessel will persist. A well's annulus system, though closed to transfer of matter, is not closed to energy transfer because it is not isolated from transfer of heat from its surroundings, therefore an allowance for small pressure changes is necessary. The test provides an immediate demonstration of whether or not leaks, detectable by these means, exist. A discussion of and procedures for the SAPT are outlined in Attachment 1.

3.1.2 The Standard Annulus Monitoring Test (SAMT)
Pursuant to 40 C.F.R. &sect 146.8(b), monitoring of the annulus pressure is an approved method for establishing part 1 of MI for all wells. Annulus pressure monitoring for Class I wells required at &sect 146.13(b)(2) to verify the maintenance of a minimum pressure differential is not the SAMT, because changes in pressure due to loss of annulus liquid are attenuated by the presence of a gas blanket which is replenished as pressure decreases. If annulus monitoring is used to demonstrate MI, an initial SAPT is required. Annulus monitoring may continue throughout the life of the well or the operator may choose, at any time, to conduct a SAPT every five years and after well reworks (on rule authorized Class II wells and on permitted wells if the particular UIC permit allows it), thereby discontinuing the SAMT. A discussion of the merits and procedures for the SAMT is provided in Attachment 2.

3.1.3 The Radioactive Tracer Survey (RTS)
On September 18, 1987, the USEPA published a Federal Register (FR) notice at 35324 et seq. FR 52, No. 181, giving interim approval for the use of the RTS as an alternative MIT. In a FR Notice at 46837 et seq. FR 52, No. 237 on December 10, 1987, the USEPA announced final approval of the RTS as a demonstration of part 1 and 2 (as limited), and provided clarifications and additional information based on comments received and the use of the test during the interim approval period. A discussion of and procedures for conducting the RTS as a demonstration of part 1 of MI in Region 5 are outlined in Attachment 3.

3.1.4 Water-Brine Interface Test (W-BIT)
On January 10, 1992, approval of the W-BIT was announced in the Federal Register at 1109 et seq FR 57, No. 7. The test is valid only for Class III wells and only when construction and operating conditions make testing with the SAPT impractical. Although there are no special recommendations applicable in Region 5, additional explanation of the basis for the test is provided in Attachment 4, and a full description of the procedures for conducting the W-BIT is available in the above referenced FR Notice.

3.1.5 Ada Pressure Test
The Ada test is a variant of the SAPT. It is used to test wells which have perforations above the injection zone. It can be used to test the integrity of the casing above the perforations. To conduct the test gas pressure is used to depress the liquid level to a point just above the perforations. The

pressure is measured over a period of time. If the pressure change is less than the established limit, the well has mechanical integrity.

3.1.6 Water-in-Annulus Test (WIAT)
The WIAT was announced at 14678 et seq 54 FR No. 19 on April 12, 1989, for existing Class II wells for enhanced oil recovery in the counties in which the Bradford oil field is located in New York and Pennsylvania. Approval of the test was extended to similar wells in the Redhaw oil field in Ashland County, Ohio. The test is used for wells which are constructed without long string casing. The level of water near the top of the annulus between the surface casing, which protects all USDWs, and the injection tubing which is set on a formation packer and may have some cement on the top of the packer, is observed under specified conditions. The presence and nature of relatively small leaks can be determined.

3.2 Mechanical Integrity Pursuant to 40 C.F.R. &sect 146.8(a)(2)

Owner/operators have a choice of a number of methods for demonstrating that wells have part 2 of MI (no significant fluid movement into a USDW through vertical channels adjacent to the injection well bore). The conditions under which these tests can be used to best effect differ significantly; therefore, a listing of relative advantages and disadvantages of the various options is provided in the attachments concerning each of the approved methods for demonstrating part 2 of MI.

3.2.1 Temperature Logs (TL)
Temperature logs are a very versatile and sensitive means of identifying fluids which have moved along channels adjacent to the well bore. In addition to demonstrations of part 2 of MI, temperature logs can be used to monitor fluid movement through the confining zone adjacent to the well bore and can often locate small casing leaks. To be effective for demonstrations of MI, there must be adequate time available for short-term temperature effects along the well bore to dissipate. Background information and general procedures for running t emperature logs are provided in Attachment 5.

3.2.2 Noise Logs (NL)
The use of noise logs is based on the observation that flow behind the casing in the well bore will, at some points, be turbulent. Turbulent flow causes noise which may travel for significant distances along the well bore. Noise logs are appropriate where it is impractical for injection operations to be suspended for the length of time needed to allow temperature stabilization to proceed to the point at which a temperature log can be run with good results. They can also be used to locate some tubing or casing leaks. Background information and procedures for using noise logs to demonstrate part 2 of MI are found in Attachment 6.

3.2.3 Oxygen Activation Method (OAL)
On February 1, 1991, the USEPA published a FR Notice (FRN)granting final approval, effective March 4, 1991, for use of the oxygen activation method or log (OAL) as a means of demonstrating part 2 of MI. Details of the operation and conditions under which the OAL can be used can be found at 4063 et seq. FR 56, No. 22 which is included in this guidance as Attachment 7.

3.2.4 Radioactive Tracer Survey
The same FRNs which describe how the RTS can be used for demonstrating part 1 of MI also describe its use for demonstrating part 2 of MI. This method may be used only where there is only a single confining formation separating the lowermost USDW from the injection zone with no aquifers within it. Additional requirements and limitations of the RTS are described in the previously mentioned FR Notices (See III.C.). The use of the RTS as a means of demonstrating part 2 of MI is described in Attachment 8.

3.2.5 Cement Records
The most common demonstration of part 2 of MI for Class II wells is based on cementing records. Demonstrations of MI for Class III wells can also be based on cementing records if the configuration of

wells prevents the use of logging methods. If records show that casings are cemented in a way which will prevent the movement of liquids into or between USDWs, the well has part 2 of MI. A discussion of the use of cementing records is provided in Attachment 9.

3.3 Additional Mechanical Integrity Tests

Other alternative MITs will be added to this guidance if approved by the Administrator of the EPA for use in Region 5. In order for a test to be approved, it must be submitted to the Water Division Director in Region 5 with all supporting evidence. If the proposal is approved by the Director, then it will be submitted to the Administrator, and will be evaluated by the national UIC Technical Workgroup which will evaluate its effectiveness. If approved by the Administrator, the approval and any limitations placed on the test will be promulgated in the Federal Register. In addition, specific procedures outlined in this guidance may be modified after additional data are obtained or to accommodate a particular type of well construction. National UIC Guidances #15 and #34 include information relating to approval of alternate methods of testing mechanical integrity.

3.4 Tests which are not MI Tests but are Specifically Required by Regulation

3.4.1 Radioactive Tracer Survey
The regulations at 40 C.F.R. 146.68(d)(2) require annual demonstrations of the integrity of cement at the top of the injection interval in Class I hazardous-waste injection wells. The RTS is more often used for that purpose than to demonstrate either part 1 or 2 of MI. The procedures for demonstrating cement integrity using the RTS are presented in Attachment 10*.

3.4.2 Casing Inspection Logs (CIL)
The regulations at 40 C.F.R. 146.68(d)(4)require periodic monitoring of change in casing thickness for Class I wells injecting hazardous wastes. The procedures for running the logs and presentation of the results are set by the logging company. Because the standards adopted by the logging companies are appropriate, no additional information is provided for running casing inspection logs.

4 CONDUCTING TESTS WITHOUT A REPRESENTATIVE OF THE USEPA

It is, and has been, the policy of Region 5 to witness mechanical integrity testing to the extent practicable. Tests for which a mechanical or third-party record is produced may be conducted without an Agency witness when it proves impossible to resolve scheduling conflicts with both the USEPA contract inspectors and the Regional technical staff.

In order to conduct testing without an USEPA representative the following procedures should be followed:

1. The owner/operator must submit proposed procedures including the information that no USEPA representative is available, and receive permission from the DI Section of the UIC Branch to proceed;
2. The test must be documented using either a mechanical device which records the value of the parameter of interest, or by a service company job record;
3. A report of the testing including all data available at the conclusion of the test and a certification of accuracy which is signed by an authorized representative of the company must be submitted to the DI Section within 10 c alendar days of the completion of testing; and
4. A final report, including any additional interpretation necessary for evaluation of the testing, must be submitted prior to or with the next regularly scheduled monitoring report or as required under the appropriate permit for the injection well.

NOTE: Pursuant to &sect 146.8(f) of the UIC regulations, Region 5 may, at any time, require a test witnessed by a USEPA representative to verify the results of an unwitnessed test. This is possible if results are ambiguous or if documentation is lacking.

5 ACTIONS TO BE TAKEN IN THE EVENT OF A FAILURE TO DEMONSTRATE MI OR LOSS OF MI DURING OPERATIONS

If upon investigation, the well appears to be lacking MI, the operator should cease injection immediately and attempt to mitigate any environmental effects of the loss of MI. The Director may allow up to 48 hours of injection if necessary to allow for a smooth shut down of operations. Pursuant to 144.28(b) or 144.51(l)(6), owners/operators are required to report any known loss of MI which might endanger health or the environment to Region 5 within 24 hours. To report a failure, operators may call Region 5 at (312) 353-4148; during nonbusiness hours a message can be left on the voice mail system. Also, pursuant to 144.28(b) or 144.51(l)(6) a written submission shall be prepared and sent to Region 5 within five days of the time the operator becomes aware of a loss of MI.

Injection into wells which have lost MI can be resumed only after a letter authorizing injection is received from the Director. The Director will prepare such a letter only if: 1) the well is repaired, a report detailing the means used to effect the repair is submitted, and MI is demonstrated or 2) the owner/operator demonstrates, by means acceptable to the Director, an absence of flow into or between USDWs pursuant to 40 C.F.R. &sect 144.28(f)(4) or 40 C.F.R. 144.51(q)(3). As an alternative, the well can be plugged in accordance with 40 C.F.R. &sect 146.10. The plugging procedures must remove any threat posed by the absence of MI. If the failure is of part 1 of MI, this is usually accomplished through cementing the leaking portion. If the failure is of part 2 the means required to eliminate the fluid movement might be more demanding.

Falsification of MI testing is a violation of 18 USC &sect 1001 and violators may be subject to criminal penalties.

ATTACHMENT 1
STANDARD ANNULUS PRESSURE TEST (SAPT)

1 Basis

Pascal's Law states that any pressure applied to a fluid filling a closed vessel will be transmitted, undiminished, throughout the vessel. This fact is the basis for the selection of the SAPT as the primary means to determine if a well's casing, tubing, packer, and wellhead (the annulus system) are liquid tight. To fully test the well bore, the pressure applied to the annulus system must be transmitted through the entire well bore. Therefore, no mechanical plug may be placed above the packer in any well subject to testing by means of the SAPT.

Because the annulus system is not an isolated system (e.g. it transmits energy, but not matter), the measured pressure applied may not be constant through time. The temperatures along the well bore must change as injection rates and temperatures change because of heat exchange between injectate and the surrounding rock. When the well is shut in part of the well bore may cool and part may become warmer. As this happens, the liquid in the annulus contracts or expands. Because liquids are only very slightly compressible, it is very unlikely that the pressure will appear to remain absolutely stable either while the well is shut in or being used for injection.

2 Advantages and Disadvantages of the SAPT

Advantages of the SAPT

1. Easy to interpret
2. Inexpensive to perform

Disadvantage of the SAPT

Provides a demonstration at a single point in time

3 Equipment and Forms

Pressure measurements must be made using a gauge which can be read with sufficient accuracy to identify pressure change which would result in failure of the test and to record accurate intervening values required per the procedures in Part D below. If the test pressure is 300 pounds per square inch, gauge (psig), then the gauge face should be marked in increments of 5 pounds per square inch (psi) or less. A gauge measuring injection pressure should be available.

The "Annulus Pressure Test" form (Attachment 11) is used to record SAPTs. Pressure measurements at intervals through the test period and the signature of an authorized witness are essential for acceptance. The most recent record of calibration for the gauge used for the MI test must be submitted along with the Annulus Pressure Test form. If authorization has been granted to conduct the test without a USEPA witness, the mechanical record of the test must be submitted as well.

4 Procedure for the SAPT:

To properly conduct the SAPT:

1. The tubing/casing annulus (annulus) must be completely filled with liquid (variations must be approved by Region 5). Temperature stabilization of the well and annulus liquid is necessary prior to conducting the test. This may be achieved by filling the annulus with liquid and either ceasing injection or maintaining stabilized injection (i.e., continuous injection at a constant rate and constant injection fluid temperature) before and through the test;

   No unapproved substances may be added to the annulus liquid. Use of any substance which might affect the outcome of testing may constitute falsification of the test procedure, invalidate the test, and may subject the owner/operator to civil or criminal prosecution;
2. After stabilization, the annuluses of Class II wells should be pressurized to a surface pressure of no less than 300 psig. The annuluses of Class I wells should be pressurized to the greater of 300 psig or a pressure which exceeds the maximum allowable injection pressure by 100 psi, unless an alternate pressure is approved by Region 5. A positive pressure differential between the pressure in the annular space and the injection tubing pressure of at least 100 psi should be maintained throughout the entire annulus (from the top of the packer to the surface) of all Class I and II wells. Specific gravity differences between liquids in the annulus and the tubing should be accounted for when determining the appropriate test pressure. Following pressurization, the annular system must be isolated from the source of pressure and the sealpot (if present) by a closed valve. If not inconvenient, the connection to the pressure source should be disconnected entirely;
3. The annulus system must remain isolated for a period of no less than 30 minutes for Class II, III, and V wells. The isolation must be maintained for one hour for Class I wells. During the period of isolation measurements of pressure should be made at ten-minute intervals; and
4. After the SAPT test period has been completed, the valve to the annulus should be opened and liquid returns from the annulus observed and measured. This may be done by allowing liquid to flow into a sealpot assembly and measuring the volume of the returns or by opening a valve and catching the liquid flowback in a container. The volume of annulus liquid returns recovered is proportional to the volume of the annulus and the amount of pressurization. The liquid return test can serve as an indication as to whether the full length of the annulus has been tested. As an alternative, the amount of liquid needed to increase the pressure can be measured. If the entire length of the annulus, from the wellhead to the packer, set at the approved depth, is not tested, then the test is void.

5 Interpretation

The interpretation and confirmation of the SAPT include:

1. Comparison of the pressure change through the test period to 3% of the test pressure (0.03 X test pressure). If the annulus test pressure changes by this amount or more (gain or loss), the well has failed to demonstrate MI (for all wells), and operation may constitute a violation

of the UIC regulations. If the annulus test pressure changes by less than 3 percent (gain or loss) over the test period, the well has demonstrated MI, pursuant to 40 C.F.R. &sect 146.8(a)(1); and

2. Evaluation of the amount of liquid returned. If less than a cup of liquid is returned, the annulus may be blocked at a shallow depth. In the past criminal charges have been brought as a result of investigations inspired by the observation that very little liquid was returned. The owing formula can be used to find how much liquid should be returned:

$dV = (P_t - P_f) \times V_f \times h \times 0.0000032$

where:
dV = the amount returned, gals;
P_t = the pressure used to test the annulus, psi;
P_f = annulus pressure after depressurization, psi;
V_f = the volume of one foot of the annulus from Halliburton table 221-B, gals;
h = length of the annulus, ft; and
0.0000032 gal/gal/psi = the compressibility of water.

The result is the number of gallons of liquid which should be returned. It is also the amount of liquid needed to pressurize the annulus to the test pressure once the annulus is filled with liquid. For a small annulus which might be typical of a Class II well (4-1/2 inch, 11.6 lb/ft. casing and 2-3/8 inch tubing, pressurized to 300 psi), just under one half gallon of liquid should be returned for each 1,000 feet of depth to the packer. If several gallons of liquid are returned, it is fairly certain that the entire length of the casing and tubing have been tested.

ATTACHMENT 2
STANDARD ANNULUS MONITORING TEST (SAMT)

1 Basis

The SAMT is essentially a continuing SAPT; however, interpretation is complicated by operational effects, principally: 1) injection tubing expansion or contraction as a result of injection pressure changes and 2) well bore temperature changes associated with a) starting or stopping injection or b) daily and seasonal changes of injectate temperature. To eliminate additional complexities, the regulations now require that the pressure be greater than atmospheric pressure.

This means that the annulus pressure should be raised to some pressure and the annulus should then be sealed. The pressure will change in response to temperature changes or even pressure changes in the injection tubing. Allowing for some seasonal variation, the range of temperature change should be consistent. In the event of a casing leak opposite a permeable zone, the pressure will normally fall, probably to zero and, if not, the range of pressure change will be much diminished because the aquifer with which the leak communicates will buffer volumetric changes in the annulus. In the event of a tubing or packer leak, the annulus pressure will track injection pressure. These two pressures will probably not be equal because of pressure loss due to friction in the injection tubing and density differences.

Region 5 Class I UIC permits require that a positive pressure differential be maintained between the annulus and injection tubing in Class I wells. The purpose of this requirement is to ensure that any leak in the injection tubing will result in an inward leak so that the injectate will not leak into the annulus. This is an important safeguard when the injectate is corrosive or very dangerous. Compliance with this requirement is not equivalent to use of SAMT if the pressure is artificially maintained through the addition of gas to a seal pot.

Unless any leak will result in an unimpeded pressure change, leaks might not be evident. To enhance the value of maintaining a positive pressure differential, Region 5 permits require volume measurement of all liquid additions and subtractions from the annulus systems of Class I wells. The results of these measurements are accumulated and a continuing need to add or remove fluid to maintain a set pressure is evidence of a leak in the well, although not necessarily an absence of MI. When a loss becomes evident, the Director may require a SAPT to confirm MI. If the well demonstrates MI, the Director may allow continued use if the leak does not cause violation of any UIC regulation.

2 Advantages and Disadvantages of the SAMT

Advantages

1. Provides a continuous demonstration of MI
2. Inexpensive for simple annulus systems
3. Easy to interpret for simple annulus systems

Disadvantages

Is difficult or impossible to interpret for wells with annulus pressure maintenance systems

3 Equipment and Forms

In order to make determinations quickly and simply, measurements of both the annulus and injection pressures should be made. Operators of Class I wells must use either an analog chart recorder or electronic equipment recording in a digital format at short intervals. Class II operators must record these pressure measurements at a frequency set by permit conditions. Other arrangements are possible, but must be established as permit conditions.

There is no set form for reporting the results of the SAMT. Each operator using the SAMT proposes a monthly reporting form to the DI Section. To effectively use the SAMT, the form must list not only the annulus pressure as measured at least once in any 24 hour period, but also the injection pressure measured at the same time. In addition, information about the injection rate, the temperature of the injection fluid, and the injection pressure may be useful. Changes in any of these parameters can affect the annulus pressure.

4 Procedure for the SAMT:

For Class I wells and other wells having a sealpot assembly and pressure maintenance the operator must:

1. Establish a positive pressure differential between the annulus and injection tubing sufficient to avoid changes which impinge on the required pressure differential (most Class I permits require at least a 100 psi pressure differential);
2. Isolate the annulus from any source of pressure maintenance;
3. Perform an SAPT, recording pressure at ten-minute intervals. If the pressure change is less than 3% in 30 minutes for Class II and III wells or 3% in 60 minutes for Class I wells, the test is passed and the SAMT begins;
4. Report the results of near-continuous measurements of annulus pressure and injection pressure in tabular and graphical formats along with tabulations of injection rate and pressure and injectate temperature as required by permit; and
5. Report the volume (in gallons) of any liquid added to or removed from the well's annulus system.

For wells not using a sealpot assembly the operator must:

1. Establish a pressure greater than atmospheric on the casing/tubing annulus;
2. Isolate the annulus from any source of pressure maintenance;

3. Perform an SAPT, recording pressure at ten-minute intervals. If the pressure change is less than 3% in 30 minutes for Class II or III wells or 60 minutes for Class I wells, the test is passed and the SAMT begins;
4. Report the results of periodic measurements of annulus and injection pressures and conditions under which pressure measurements are made, e.g. injecting or not injecting, and approximate injectate temperature; and
5. Report the volume (in gallons) of liquid added to or removed from the well's annulus system.

After any well failure, MI must be confirmed using the SAPT before resuming the SAMT.

5 Interpretation

The standard used for evaluating SAMT demonstrations is the same as that used for the SAPT, i.e., 3% pressure loss in either 30 or 60 minutes. However, it is only possible to apply this standard when external factors which might affect the annulus pressure are stable and a change in annulus pressure is established. Otherwise, liquid property changes occurring in response to change in ambient conditions make determination of a leak-induced pressure change impossible.

To provide an effective, real-time demonstration of MI, frequent inspection of pressure records is needed. This review should focus on the pressure in the annulus relative to: 1) atmospheric pressure, 2) the injection pressure measured at the surface, and 3) pressure in aquifers along the well bore. The following occurrences may indicate a loss of MI:

5.1 For wells with injection pressure greater than the annulus pressure

1. Annulus pressure increases and tracks injection pressure - probable tubing or packer leak;
2. Annulus pressure decreases:
    a. and goes to near zero - probable casing leak;
    b. stabilizes and returns to normal behavior - possible packer slip;
3. Annulus pressure is very stable regardless of injection - probable deep casing leak in well with light annulus liquid;
4. Annulus pressure fluctuates - probable temperature effects due to operational effects of injectate temperature changes;

5.2 For wells with injection pressure greater than zero but less than annulus pressure

1. Annulus pressure increases - if the well is deep, penetrates high pressure zones, and the annulus liquid is light it may indicate a deep casing leak, possibly due to an increase in injectate temperature;
2. Annulus pressure decreases:
    a. to near zero and/or becomes very stable - probable deep casing leak in well with lighter annulus liquid;
    b. and tracks injection pressure - probable tubing leak;
    c. stabilizes, and resumes normal behavior - could be a decrease in average injectate temperature or packer slip;
3. Annulus pressure fluctuates - probable temperature effects due to operational effects of injectate temperature changes;

5.3 <u>For wells which inject on a vacuum</u>

1. Annulus pressure decreases - could be either a casing, tubing, or packer leak;
2. Annulus pressure increases: and
    a. stabilizes - if the well is deep, penetrates high pressure zones, and the annulus liquid is light it may indicate a deep casing leak;
    b. begins to behave normally at a higher pressure - possibly due to an increase in injectate temperature.

In the event that a loss of MI is suspected an SAPT should be performed to ensure that the well has MI. If the SAPT confirms MI, then the operator may resume the use of the SAMT.

ATTACHMENT 3
RADIOACTIVE TRACER SURVEY (RTS)
FOR DEMONSTRATION OF 146.8(a)(1)

1 Basis

During injection, radioactive (RA) tracers can be added to injected liquids at a point above the interval to be checked for leaks. The RA material will mix with a portion of the injectate so that a slug of RA injectate passes through the section of the well to be tested. Any leak of the mixed injectate will be marked with some RA tracer. The leaked tracer material may be traced using a detector device on a wire line. The movement of the leaked tracer material is unlikely to keep pace with the movement of the slug of marked injectate which continues down the well and will be identifiable.

When tracer material is observed to split, the movement of the portion which appears to have separated should be carefully traced. The most accurate way to do this is by positioning the detector ahead of the moving tracer and observing its passage. When the tracer fails to arrive at the detector, the upper limit of movement is fixed. This method is superior to chasing the slug because it appears to be more sensitive and the record does not distort the shape of the slug as a result of tool movement. However, great care is needed to identify small increases in gamma ray activity.

2 Advantages and Disadvantages of the Radioactive Tracer Survey

Advantage
Locates the depth of the leak within the well bore

Disadvantages
1. Expensive relative to SAPT
2. Approved testing methods always require injection. Velocity shots used for the location of very small leaks may be used without injection, but require long periods of investigation

3 Equipment and Reporting Forms

The equipment required is readily available. In the past, almost any company engaged in geophysical logging was able to conduct RA tracer surveys. Some companies have discontinued the service due to restrictions imposed on the handling of RA material. The equipment consists of a sonde (tool) which is lowered into the well on a cable which allows transmission of data from the tool to receivers in a winch/instrument truck on the surface. The tool consists of an injector stage, one or more gamma radiation detector devices, and a collar locator.

The relative positions of the injector and detectors are variable. If only one detector is used, it must be located below the ejector. If more than one is used, it is common and advantageous for one detector to be located above the ejector. Three detectors are sometimes used with two being below the detector. This allows very accurate measurement of the speed of the injectate to be made. It also simplifies the location of the upward limit of leaking by eliminating some repositioning of the tool.

The purpose of the collar locator is to pinpoint the location of leaks in reference to permanent markers. This may also be done by means of correlation to a gamma ray trace which is scaled to show lithologic effects. Using a collar locator immediately lets the analyst know whether an identified leak is at a collar, while using a gamma ray correlation log clarifies the stratigraphic location of the leak.

The RA tracer is usually Iodine 131, because of its short (eight day) half life. Other tracers may be used for special applications. In any case, the tracer material used must be anionic to minimize its molecular attraction to well and rock materials.

In addition to the log of the test as presented bythe service company which performed the test, the digital data from which the log was produced must also be submitted. Information which is helpful to interpretation should be reocrded on the log form, including: 1) a schematic drawing or description of the configuration of the tool, 2) the injection rate, 3) the time at the beginning and end of each logging run, and 4) the time at which any peak is recorded. It is also helpful to use time markers on the logs to accurately fix the times at which changes in radioactivity are recorded.

We request that logging engineers review the information sheet which will be returned to permittees along with approval of procedures so that they will provide the informatiion needed to fully interpret the logs. The information sheets need not be filled out and returned.

Further testing may be necessary if possible migration out of an authorized injection interval is noted. This may include a series of time drives and slug chases to determine the extent of the leak or channel.

4 Procedures for Running the Radioactive Tracer Survey (RTS) as a Demonstration of Part 1 of MI

The demonstration can be effective for locating leaks in both the tubing and the casing. However, the RTS is useful for demonstrating an absence of leaks only in tubing strings through which the tracer material may flow. A demonstration that there are no leaks in the tubing requires that steps 1 through 8 listed below be followed. To test the casing, the tubing may be removed and the same steps followed, or the packer may be unseated and the method used to check cement integrity, described in Attachment 10, may be followed.

Testing is always conducted while injecting, and the operator should ensure that adequate water can be supplied for the test. The injection rate may be governed by the ability of the winch operator to track the RA slug as it moves downward. However, the injection rate should be as close to the maximum injection rate as practical. The following practices usually result in interpretable results:

1. Ensure that there is a significant pressure differential across the tubing wall to be tested. If the tubing is to be tested, special permission may be needed to perform the test with excess pressure in the tubing, because permits may require a positive pressure differential within the annulus. Although introduction of tracer material into the annulus can allow testing while maintaining a positive pressure differential, testing within the range of USDWs defeats the purpose of the positive pressure differential, because a casing leak would allow a release of radioactive material into an USDW. Further, practical difficulties make testing with the tracer in the annulus a complex operation;
2. Set the gamma ray (GR) detector sensitivity so that lithologic effects are just identifiable, usually 25 to 50 counts per second per inch. This ensures maximum sensitivity to leaked RA material. Noisy logs are much more difficult to interpret;
3. Make a background GR log over the interval to be tested before any RA material is introduced into the well;
4. Record measurements over a period of three to five minutes with the tool stationary at two points which are representative of the extremes of natural radiation within the interval to be tested. This will allow the interpreter to observe the effects of natural variations of GR emission on the record;
5. Release a slug of RA material above the interval to be tested. The greater the intensity of radioactivity of the slug the more resolution the method will have. Deflections caused by the slug should be 50 times greater than those caused by lithologic effects;
6. Follow the slug with the logging tool or make repeated passes upward through the slug as it moves down the well. Any increase in radioactivity which remains behind the slug should be investigated by supplementary passes through the interval as needed to determine whether

it is a result of material adhering to the tubing or of a leak. All logging should be done at a single logging speed which is appropriate for the injection rate to allow quantitative measurements of deflections to be evaluated

7. If repeated passes are used, the logs resulting from the slug-tracking exercise should overlap so that the return of radioactivity to the level which existed before the slug's passing is demonstrated for the entire length of the section of the well being tested. The logs of all passes should be presented as a composite log on a common depth track. If means to differentiate the log traces are available no other presentation is required. If the traces cannot be differentiated on the composite log, they should also be presented individually;
8. After any ejection, the slug should be followed until it has moved below the interval being tested. If the slug splits, both slug portions must be accounted for. This can be accomplished by concentrating first on the upward moving portion, and resuming tracking of the downward moving slug after the upward moving slug is tracked to its final destination; and
9. After completion of the passes, a final log should be made through the entire tested interval to check for residual radioactivity which might be associated with exit of tracer material from the well bore.

If the tubing has been removed from the well and the casing is being tested, leaked RA material will exit the well bore into a porous, permeable zone or fracture or move along the well bore to a porous, permeable zone or fracture. The movement of the tracer should be followed and the depth at which it exits the well bore recorded.

Leaks in the casing can be located with the tubing in the well by monitoring for upward movement at the base of the tubing with the packer released, as described in Attachment 8. Except in the unlikely case that the pressure in the aquifer with which a leak allows communication is higher than the injection pressure at the same depth less the friction loss from the leak to the end of the tubing, an absence of upward movement when the top of the annulus is sealed, means that there is no leak in the casing. However extreme care must be taken to ensure that upward movement will be identified. A release of a longer- period slug may increase the strength of the upward moving slug. Any upward movement of RA tracer will continue until the tracer reaches the leak and exits the well bore.

If the operator wishes, the portions of the injection interval which accept waste may be determined by making more frequent passes while the slug is within the injection interval. The sensitivity may be reset so that the log trace remains on scale.

5 Interpretation

1. Where a measurable amount of RA tracer material leaks from the tubing, it will be observed as a small area of increased radioactivity after the slug has passed;
2. If an area of elevated radioactivity is observed, additional runs should clarify what becomes of the RA material responsible. This will demonstrate whether only the tubing is leaking, or both the tubing and casing lack integrity. In most cases, if a well's casing has integrity but a tubing leak exists, pressure equalization and cessation of leaking will occur until a change in injection pressure allows the leak to resume. This is why it is important to ensure a pressure differential between the injection tubing and annulus.

   If annulus pressure is lower than injection pressure and both the tubing and casing are leaking, any tracer material that leaks out of the tubing will generally move toward and out through the casing leak. This is because the annulus pressure normally will be higher than the hydrostatic pressures within adjacent formations at all depths.

   If only the tubing is leaking, the tracer material will remain near the leak, spreading slowly both up and down from the leak location.

   Adherence of tracer material to the tubing can be differentiated from a tubing leak because any material adhering to the tubing will eventually be washed away with no movement evident.

If no evidence of leaking is observed, the well has demonstrated part 1 of MI. Be aware that demonstrations of MI using the RTS will be examined very closely, and any conditions which threaten the ability to interpret them accurately must be removed.

ATTACHMENT 4
WATER-BRINE INTERFACE TEST (W-BIT)

1 Basis

The water-brine interface test is based on:

1. The differences in liquid pressure gradients of the brine filling salt solution mining caverns and fresh water;
2. Pressurization of the cavern resulting from salt-solution mining; and
3. Pascal's Law, the transmission of pressure throughout a closed vessel.

The strategy governing the test is that a decrease in wellhead pressure will be observed in the event of loss of a fluid of lower density filling a standpipe open to a reservoir filled with a fluid of higher density. In practice, this situation is produced by:

1. Flushing the well to be tested with sufficient fresh water to dissolve any salt precipitated on the interior of the casing;
2. Withdrawing water until cavern brine is brought to the surface; and
3. Depressing the cavern brine to the base of the well casing by the injection of a volume of fresh water sufficient to fill the casing to within 25 feet of the casing shoe.

Because the cavern is pressurized sufficiently to cause the heavy brine to flow to the surface, the pressure within the well filled with fresh water is greater than the hydrostatic pressures in any aquifer through which the well passes. Therefore, any leak will allow fresh water to flow outward, to be replaced by dense brine flowing into the well from the cavern. Because the liquid pressure gradient of the brine from the cavern which replaces the leaked fresh water is greater than that of the freshwater, less pressure is transmitted from the cavern upward through the well to the well head.

It has been found that pressure within the cavern is not constant. To avoid the possibility that this variation might mask any change due to leakage, a reference well is used. This well, which is often the tubing within the well being tested, is filled with a static fluid column. If there is a leak in either the tubing or the casing, fresh water will be lost from the annulus. While the rate of leakage into the tubing is likely to be less than would be leakage from the casing, due to a lower pressure differential, particularly if the leak is near the base of the casing, the resultant emplacement of fresh water into the tubing will increase the wellhead pressure so that the effect is doubled.

The loss of one foot of annulus liquid during the W-BIT will cause a wellhead pressure reduction of approximately 0.11 psi:

$dP = dL \times (0.433 \text{ psi/ft.} - SG_c \times 0.433)$

$-0.11 \text{ psi} = 1 \text{ ft.} \times (0.433 \text{ psi/ft.} - 1.25 \times 0.433 \text{ psi/ft.})$,

where:
dP = pressure change resulting from fluid loss,
0.433 psi/ft. = pressure gradient of fresh water (SG = 1.0),
and
SG_c = specific gravity of cavern fluid = 1.25,

while the loss of one foot of pressurized annulus liquid from an annulus 1,000 feet in length will cause a loss of 312.5 psi:

dP = dV/V/0.0000032 ft./ft./psi

-312.5 psi = -1 ft./1000 ft./0.0000032 ft./ft/psi.

where:
dP = pressure change,
dV = volume leaked = -1 ft.,
V = annulus volume = 1000 ft., and
0.0000032 ft./ft./psi = the compressibility of water.

The test must be run for a longer period than the SAPT and measurements must be much more accurate to compensate for the lesser pressure change associated with leaked volume.

2 Advantages and Disadvantages

Advantages

1. Does not require removal of tubing and installation of a packer for wells used for injection and withdrawal of liquids;
2. Inexpensive for simple annulus systems.

Disadvantages

1. The W-BIT is approved only for Class III wells which cannot be tested by means of the SAPT
2. Requires use of a deadweight pressure gauge, which may be expensive to acquire;
3. Requires a 36-hour interval between initial and final pressure measurements.

3 Equipment and Forms

A dead weight pressure gauges and an operator trained in its use are needed. A convenient worksheet has been developed by members of the Salt Institute.

4 Procedures

The UIC Branch has not identified any common errors in conducting the W-BIT, and we believe that no additional guidance is needed beyond that provided in the Federal Register notices announcing its approval. A schematic drawing of the well construction must be submitted with a description of the proposed test procedures.

5 Interpretation

The calculations which are part of the test result in the calculation of a rate of pressure change. If this pressure change is less than 0.05 psi/hr., then the test demonstrates the MI of the tested well. If the rate of change is more than the standard, the well lacks MI.

ATTACHMENT 5
TEMPERATURE LOG (TL)

1 Basis

In almost every case, an aquifer into which water has flowed in the recent past is heated or cooled because the earth's temperature increases steadily with depth. This makes it unlikely that the water moving into a reservoir is the same temperature as that which is displaced. Given sensors of sufficient sensitivity, the change in temperature is identifiable. In addition, the zone from which the water came is likely to be identifiable if flow is continuing. Temperature logs can also confirm that there is no flow of injectate through the rock surrounding the well bore and often will identify small casing leaks.

During injection the ability of the injectate flowing through the well to maintain its own temperature dominates all other effects so that, for the purpose of establishing MI, the well must be shut in during temperature logging. The principal requirement for running temperature logs is that the well be shut in long enough so that temperature effects related to well construction can dissipate, leaving a relatively simple temperature profile. Experience has shown that 36 hours is usually sufficient in Region 5.

In new wells, baseline temperature logs should be made as long as possible after drilling the well, but before injection begins, because temperature effects due to circulation of drilling fluid will persist for several weeks after drilling is completed and infiltration of drilling fluids causes temperature anomalies which may persist for several months. A;though these anomalies can makr permeable zones, the existence of a temperature log which reflects the natural geothermal gradient can be of great value in assisting later analyses and for understanding other geophysical effects.

2 Advantages and Disadvantages of Temperature Logging

Advantages:

1. Continuous log with high vertical resolution
2. The most sensitive indicator of part 2 of MI
3. In addition to fluid movement within the well bore, fluid migration through the confining layers may be identified
4. Water-filled porosity can be determined if sufficient information is available
5. Injection pressure need not be maintained to ensure identification of well bore flow near the injection interval
6. Flow need not be occurring at the time of logging for its effects to be identifiable
7. Low cost per single survey covering entire well bore

Disadvantages:

1. Gas entry may be marked by cooling, but movement and exit may be obscure
2. Interpretation for complete understanding requires a greater degree of expertise than other logging methods
3. Fluid-filled well bore through interval to be tested may be required
4. Well must be shut in long enough to remove most construction and near-well bore effects

3 Equipment and Reporting Forms

The temperature logging tool is a wireline sonde operated from a winch truck. Temperature logging tools contain circuitry which responds to temperature change by changing resistance to current flow. The response is linear and temperature logs can distinguish very small changes in temperatures. Calibration of logging tools is often poor because the effects they are normally expected to measure have importance as relative rather than absolute values, although correct absolute temperatures also have value for other purposes. To be effective, temperature logging tools must have good thermal coupling to the borehole environment, which means that they are not generally useful in air-filled

holes. Sampling is done at short intervals as the sonde is lowered into the well, so that a record of the entire well bore is produced. Because the tool does not react to temperature change instantaneously and the tool is continuously moving, the measured temperature changes lag actual wellbore temperature changes by a consistent amount. The more slowly the tool moves, the closer are the measured temperatures to actual temperatures. If the tool speed is erratic, the recorded temperature profile will also be irregular. Despite the possible inaccuracies due to poor calibration and tool response time, the absolute values recorded can generally be compared with some confidence.

A reporting form has been developed to accompany the log to assure that other information useful for interpretation is submitted. Alternatively, all the information requested on the reporting form can be placed on the log. This includes: average and amximum logging speed, time since the last injection, temperature of the liquid most recently injected (average temperatures for the most recent year, month, and day) and calibration information. If there are frequent changes in the temperature of the injectate or if process changes have caused a significant change in the temperature of the injectate, it is very important to record the average temperatures of the injectate before existing logs were made and the date of the change in injectate temperature and the volume of liquid injected before and since that time. In the case of Class III wells, it is important to note whether the well was last used for injection or production.

The scaling of logs is a matter of importance. Features of significance are emphasized by compressing the depth scale and expanding the temperature scale. A depth scale of one or two inches per 100 feet, and a temperature scale of one inch to two degrees Fahrenheit are appropriate in almost every case.

If multiple logs are run while shut in, they should be displayed on the same axes (depth scale) for comparison. To avoid confusion, it may be necessary to reduce the temperature scale, but reducing it to less than four degrees per inch should be done only when necessary to avoid superimposing logging traces which cannot then be followed.

Gamma ray logs must be run simultaneously with the temperature log. Gamma ray logs provide depth control and important information about the rock types along the well bore. The digital logging data must also be submitted. We request submission of data collected at intervals of one foot. More frequent readings increase the volume of data, but increased resolution serves no purpose.

4 Procedures for Running the Temperature Log

The following steps should be followed for effective temperature logging:

1. Shut well in for sufficient time for temperature effects resulting from well construction features to dissipate. This typically requires at least 36 hours in Region 5. If 36 hours prior to logging are not available, proof that sufficient time has elapsed can be demonstrated by comparison with another log of a well at the same site. The second log may have been made previously or a second log may be made six hours after the first;
2. Calibrate the log if at all possible. This can be done by comparing measurements made using the tool in any two liquids to the known temperatures of those liquids. For instance, both a thermometer and the thermistor to be used for the logging may be used to measure the temperature of water at ambient conditions and a bucket of ice water. Even a single measurement made in a well-mixed bucket of ice water may be very helpful;
3. Log the well from the surface downward, lowering the tool at a rate of no more than 30 feet per minute. The 30 feet per minute limitation is a practical balance between the tool response time and normal time constraints, slower speeds provide increasing detail. Time coding of the log, either a tick or gap in the log grid at one minute intervals or a logging-speed trace, should be used to confirm the tool speed;
4. If the well has not been shut in for at least 36 hours before the log is run, comparison with either a second log run six hours before the time the log of record is started or a log from another well at the same site showing no anomalies should be available to demonstrate normal patterns of temperature change.

5. The log data on a disc in either LAS or ASCII format is needed for ease of interpretation. A gamma ray log, made at the time of logging, or from a previous logging, and correlated to the temperature data is needed for accurate interpretation.

5 Interpretation

Confirm the validity of the log at the well site by comparing two logs made at the same site. When lithology and injectate characteristics are similar, then thermal effects along the well bore should also be very similar. After the temperature effects caused by casing joints, packers, well diameter, casing string differences, and cement have dissipated, the temperature profiles should be similar, although not identical. If construction features are evident, a longer shut-in period is probably needed.

Identification of flow is based on relative differences between logs of nearby wells if such logs exist. Although the gradients may be quite different as a result of differing injection history, their relative positions should be obviously consistent. Lithologic effects which show up on one log should show up similarly in other wells at the same site. Failure of logs made at the same site under conditions which should result in thermal stability to compare coherently constitutes an anomaly.

If there are no logs suitable for comparison, then deviations from a predictable geothermal gradient, modified by the effects of injection, are anomalies. These may take the form of a nearly constant temperature between reservoir strata. When more than one log is run, these anomalies are likely to grow (be left behind) as the profile returns toward the natural geothermal while relative differences between the traces elsewhere decrease. In addition areas with active flow will reach a stable temperature more quickly than other areas. If the movement is not related to injection, this temperature should be that of the natural geothermal gradient at the depth of the source reservoir.

If there are anomalies, a failure of MI may be indicated. In such a case, an additional new log may be necessary to show whether forms apparent on the log just made are evolving toward the forms established on the log from another well. Comparison of these two new logs should show increasing parallelism along the cased well bore, if not, then there may be flow along a channel adjacent to the well bore. If this flow results in the movement of liquid into or between USDWs, then the well does not have part 2 of MI. If the well is used to inject hazardous wastes and flow results in movement of fluid from the injection zone into the confining zone, then a release from the solid waste management unit is indicated. In the event that there are unresolved anomalies which might indicate an absence of part 2 of MI, another approved method must be used to confirm the absence of flow into or between USDWs.

Depending on the nature of the liquid movement, radioactive tracer, noise, oxygen activation, or other logs approved by the Region may be used to further define the nature of the fluid movement.

Identification of flow behind the casing is always made from long-term shut-in logs. The resolution of long-term shut-in logs for identifying the presence of flow is greater than that of logs made during injection. The temperature gradient within a well which has been injecting for some time is very shallow. The temperature at the injection zone may be only a few degrees different from that at the surface. The presence of a flow behind the casing will result in a fractional change in this gradient which will be proportional to the ratio of the flow rates within and outside the tubing. Therefore, only a rather substantial flow can be identified using logs made during injection.

ATTACHMENT 6
NOISE LOG (NL)

1 Basis

Channels along well bores are very rarely uniform. When flow is occurring, irregularities in channel cross section usually result in generation of some turbulence which occurs in audible ranges. Sonic energy travels for considerable distances through solids, allowing sensitive microphones to detect the effects of turbulent fluid flow at considerable distances. Different types of turbulence result in sounds having different frequencies. Single phase turbulence results in low frequency sounds, while two phase turbulence usually results in high frequency sounds. High pass filters are used to determine the intensity of detected noise within various frequency ranges.

2 Advantages and Disadvantages of Noise Logs

Advantages:

1. Relative to oxygen activation log, it is practical to increase vertical resolution by increasing spacing density
2. Can identify flow of gas and differentiate it from liquid flow
3. Relative to temperature logs, cannot be used to demonstrate confinement

Disadvantages:

1. Can identify only turbulent flow
2. Relative to temperature logs, cannot be used to demonstrate confinement
3. Requires liquid in well bore through the interval to be tested
4. Injection pressure must be maintained to ensure identification of fluid flow near the injection zone
5. Actual logging time and cost are usually greater than for temperature logging

3 Equipment and Forms

Noise logging tools are wireline tools which are essentially sensitive microphones. Sampling is done in a stationary mode and the time required at each station is approximately 3-4 minutes. Any sounds detected are transmitted to recorders which measure the amount (loudness) of sonic energy received over a period of time. A cumulative measure of the sound energy which has been received is recorded.

Sonic energy travels considerable distances through solids so sampling can be done in a reconnaissance mode, with additional stations run where increases in energy are detected so that exact locations of conditions which cause sonic events can be found. Sonic logs are similar to temperature logs in that they are much more effective in liquid-filled holes because of improved coupling.

The log is the only form which must be submitted. When the level of sound is low, a linear scale is used, and when there are intervals with higher sound, a logarithmic form is used. Either is acceptable. The vertical scale should be small, one or two inches per 100 feet. In addition to the graphical log, a tabulation of sound energy is normally included on the log form and it should also be submitted.

4 Procedure for Producing the Noise Log:

Noise logging may be carried out while injection is occurring in many wells because flow restriction caused by the logging tool is often insufficient to cause turbulence. It is especially desirable to log while injecting when looking for flow resulting from pressure increase near the top of the injection zone. If ambient noise while injecting is greater than 10 mv, injection should be halted. Logging procedures should include the following steps:

1. Make noise measurements at intervals of 100 feet to create a log on a coarse grid;

2. If any anomalies are evident on the coarse log, construct a finer grid by making noise measurements at intervals of 20 feet within the coarse intervals containing high noise levels;
3. Make noise measurements at intervals of 10 feet through the first 50 feet above the injection interval and at intervals of 20 feet within the 100-foot intervals containing: 1) the base of the lowermost bleed-off zone above the injectioninterval, 2) the base of the lowermost USDW, and 3) in the case of varying water quality within the zone of USDW, the top and base of each interval with significantly different water quality from the next interval;
4. Additional measurements may be made to pinpoint depths at which noise is produced; and
5. Use a vertical scale of 1 or 2 inches per 100 feet.

5 Interpretation

The interpretation of noise logs for the purpose of demonstrating part 2 of MI is quite straightforward. The following steps are used:

1. Determine the base noise level in the well (dead well level);
2. Identify departures from this level. An increase in noise near the surface due to equipment operating at the surface is to be expected in many situations;
3. Attempt to determine the extent of any movement, this may be difficult when there are few flow constrictions;
4. If flow is into or between USDWs, a lack of mechanical integrity is indicated. If flow is from the injection zone of a hazardous-waste disposal well into or above the confining zone, failure of containment is indicated.

If the log measurements are ambiguous, the determination should be confirmed using another method.

ATTACHMENT 7
OXYGEN ACTIVATION METHOD

1 Basis

The oxygen activation method is based on the ability of the tool to convert oxygen into Nitrogen 16 (N16) within a short distance of the tool. This is accomplished by emitting high energy neutrons from the tool's neutron source. N16 is an unstable isotope of nitrogen which is referred to as activated oxygen. The half life of activated oxygen is just 7.13 seconds, and the release of gamma rays as the activated oxygen decays into oxygen can be measured. If the tool is stationary and oxygen is activated, detectors placed near the activator device will detect increased gamma radiation. The intensity of the additional radiation will be inversely proportional to the square of the distance of the activated oxygen from the detector. Much of the oxygen near the tool occurs in water. If water containing activated oxygen moves, the measured intensity of radiation will be greater if the slug of activated oxygen moves closer to the detector, and less if it moves away. By comparison of intensity of gamma radiation measured as a result of activation at two detectors, the direction and velocity of water movement can be determined. Studies under controlled conditions have shown that water velocities between two and 120 feet per minute can be measured.

2 Advantages and Disadvantages

Advantages:

1. Interpretation is a simple comparison of a calculated velocity to a minimum velocity which the tool is able to identify reliably
2. Relative to temperature logs, little or no shut-in time is required
3. Does not require a liquid-filled well bore
4. Numerical result eliminates the need for qualitative interpretation

Disadvantages:

1. Can identify flow in a broad, but fixed, velocity range
2. Has a very small range of investigation, smaller than very large well bores

3. Cannot be used to demonstrate the absence of liquid movement through confining layers
4. It is not practical to increase vertical resolution by increasing spacing density
5. Calibration errors may affect tool accuracy, perhaps accounting for false positive indications
6. History includes false positives and missed MIT failures confirmed by one or more other tools
7. Injection pressure must be maintained to ensure identification of fluid flow near the injection zone
8. Actual logging time and cost are usually greater than for other logs

3 Equipment and Forms

The equipment consists of a wireline sonde containing a high- energy neutron generator and gamma ray detectors. By spacing several detectors at increasing distances from the oxygen activation area interpretational accuracy is increased. Although the oxygen which is activated may be present in water which may be moving along the well bore, oxygen is also present in rock and cement. Some of this oxygen is also activated, and its decay products become background radiation which must be accounted for in order to reach a valid measurement of the movement of activated atoms in the fluid passing along the well bore.

The need to account for oxygen which is not in flowing water can be addressed in either of two ways: 1) by making calibration measurements in a representative area of the well bore in which there is thought to be no flow behind the casing, or 2) by extending the measurement period at each station beyond the time during which the activated oxygen in flowing water has been carried away. The rate of decay indicated by the late measurements is used to calculate the theoretical levels of gamma radiation which would have been measured if there were no water movement. The difference between the calculated and measured values is assumed to be the effect of the decay of activated oxygen carried to the vicinity of the detectors as part of moving water.

The first method is used by Western Atlas and the second by Schlumberger. These are the only companies which provide oxygen activation logging service in Region 5.

4 Procedures for Running the Oxygen Activation Log (OAL):

All measurements should be taken for periods of at least five minutes with the well injecting at the maximum normal rate. A total of at least 15 minutes measurement time is required at each station. This total time may be accumulated in one, two, or three episodes. If open-hole caliper logs are available, care should be taken to obtain all readings at depths where the well bore is in gauge. The method for obtaining measurements shall conform to optimum procedures contained in the operator's manual for the tool being used. The following steps are recommended for demonstrating part 2 of MI using the OAL:

1. Secure a log for lithology determination. If no such log is available, run a gamma ray-neutron log to identify porous intervals;
2. If required for tool calibration, background checks will be run with no injection occurring in an interval where no flow is thought to occur. Background calibration should be run for each interval of varying well construction;
3. Take measurements at stations at least 10 feet above the open injection interval;
4. Take measurements at the top of the confining zone and at two or three formation changes between the confining zone and the base of the USDW;
5. Take measurements within 50 feet below the base of each USDW, within 50 feet of the top of the first underlying aquifer, and at least one measurement between these two points;
6. If anomalies are found, additional readings, including readings made while the well is injecting if the original measurements were made while not injecting, or not injecting if the original measurements were made while injecting, should be made above and below the depth of the anomaly to confirm the anomalous reading and discover the extent of fluid movement; and
7. If flow is indicated, another log may be used to confirm the measurement and define the extent of flow. The choice for the confirmation log should be based on all wellbore and

environmental factors, and the tool choice must be approved by Region 5 prior to commencing testing operations.

5 Interpretation

A ratio of the short-spaced flow indicator result to standard deviation of 3-4:1 indicates flow. Indicated water-flow velocities should be in excess of two feet per minute, lower values should be viewed with skepticism. Velocities near and above two feet per minute have been measured at several depths at several sites in Region 5 and other logs did not indicate flow. In some cases the occurrences were repeatable, at least during the period of one logging episode. Although the cause of the false measurements is not known, it is assumed that the logging tool was not properly calibrated for the interval being tested.

To minimize false positives, it is recommended that all measurements be confirmed at several nearby depths and/or measurements be taken under a minimum of 3 varying injection rates, i.e.: 75%, 50%, and 25% of maximum permitted injection rates. Before costly measures are taken to remedy problems, their existence should be confirmed using another approved log.

ATTACHMENT 8
RADIOACTIVE TRACER SURVEYS
FOR DEMONSTRATING PART 2 OF MI

1 Basis

Acceptance of the test as a means for demonstrating part 2 of MI is limited to those wells where there is no aquifer between the injection zone and the base of the lowermost USDW and where there is no significant water quality difference between individual USDWs.

The basis of the test is that flow will follow the well bore upward if the cement seal is poor at and above the base of the casing for open-hole completions or above the uppermost perforation for perforated completions. If the cement at the top of the injection interval is sound and there is no movement upward along the casing at that point, it is assumed that there is no alternate conduit which might allow injected liquids to reach the well bore at a shallower depth and then travel upward through either an uncemented or ineffectively cemented well bore. The analyst is primarily concerned with identifying the uppermost depth at which tracer material can be seen to be moving within and then exiting the well bore.

2 Advantages and Disadvantages

Advantages:

1. Can be run with the well injecting

Disadvantages:

1. Only valid for part 2 when there are no aquifers between the base of the casing and the base of the lowermost USDW and no significant differences between quality of the USDWs
2. Cannot be used to determine interformational flow where the tracer material cannot be introduced into the flow stream outside the casing

3 Equipment and Forms

These are identical to those described for the RTS in Attachment 3.

4 Procedures for Running the Radioactive Tracer Survey (RTS)as a Demonstration of Part 2 of MI

The demonstration of mechanical integrity requires that the packer be seated or the tubing be removed from the well.

Three different test methods are usually employed at each instance of testing: 1) slug tracking, 2) stationary testing, and 3) comparison of logs run before and after the other testing methods are used. Either slug tracking or the stationary tests are adequate tests, but the comparison of logs run before and after the injection is only supplementary, and its use is in identifying the intervals along the well bore where RA material has adhered to the walls as it exited the well bore.

4.1 Recommended procedures for the use of the slug tracking method are:

1. Inject at the maximum rate used for injection unless it is impossible for the tool can be effectively used at that rate. Otherwise inject at the maximum rate at which the winch operator can track the slug;
2. Release a slug of RA tracer far enough above the base of the casing or perforations to allow it to be logged within the casing at least once;
3. Drop the tool down through the slug and then log upward through the slug;
4. Drop the tool down to within 20 feet below the top of the perforations or base of the casing (or tubing tailpipe, if that is lower). Hold the tool at that point until the slug reaches it. As soon as the slug is detected, begin to log upward so that the logging tool passes the top of perforations or the base of the deeper of the casing or tubing just after the slug has passed the same point. This helps to ensure that any upward movement is detected;
5. Drop the tool below the slug, but no more than 50 feet below the perforations/casing/tubing if a split was observed during the previous logging run, and again log upward;
6. Continue making passes to show the upward movement of the slug as long as it is measurable;
7. The procedure (Steps 1 though 6) should be repeated until the highest point to which injectate moved upward is identifiable; and
8. If any slugs are seen to split, the tracer material remaining after all of the planned testing is done should be ejected just above the casing shoe and the resulting slug followed upward as far as possible.

4.2 Recommended procedures for the use of the stationary method are:

1. Injection should be at the maximum rate used to inject waste. The slug of RA material should be ejected some distance above the depth at which the stationary test will be made in order to eliminate electrical effects associated with the ejection which sometimes mask or distort the detection of the downward moving slug. The greater deflection caused by the slug, the better. However, the length of the ejection should not be over a few seconds to avoid producing a long slug.
2. With at least two detectors, one above and one below the ejector, recording in time drive, position the logging tool with the lower detector four feet above the top of the perforations or the deeper of the base of the casing or tubing. When used with slug tracking, position the upper detector about two feet above the highest point reached by the tracked slug;

   The use of at least two detectors has two important advantages: 1) it allows the test to be, in effect, run at two or more depths and may cut the time required to run a test which completely defines the upward distance a slug travels and, more importantly, 2) confirms the direction of travel of any RA material observed after the slug is ejected. Often ejectors leak a small amount of tracer. The direction of movement of extraneous slugs passing by a single detector cannot be determined and may confuse interpretation.

   The scaling should allow the easy calculation of time period and deflections should not be smeared out over so much paper that they are difficult to identify. The time scale should not be compressed so much that determining the time, to at least the minute, at which the increase in radioactivity begins is questionable;
3. The tool is run in time drive for a period sufficient to allow the RA material to reach the perforations, casing shoe, or end of the tailpipe and travel upward to the detectors assuming upward movement at a rate of no more than two feet per minute;

4. If upward moving RA material is detected, following the detection of the slug at the top detector, move the tool upward a short distance and again record in time drive until the RA material is detected. Record the times at which the RA material reaches the detectors to help evaluate how far the detectors should be moved;
5. Continue to monitor the upward movement of the slug until the limit of upward movement is reached. The limit can be considered to be the elevation of a detector which did not record passage of the slug after allowing travel time of two minutes per foot from the point of last detection.

4.3 Recommendations for producing the logs before and after testing are:

1. The log should cover the interval between at least 100 feet below the bottom of the deeper of the casing or tailpipe depth and 200 feet above the shallower of the casing or tailpipe depth.
2. A gamma ray log should be on hand to ensure that the new log reflects background conditions. Occasionally tool leaks cause anomalous results which can be avoided simply by repeating the logging.
3. A presentation including both logs on the same depth scale is helpful. The traces must be coded so as to be clearly identifiable.
4. The log data on disk should be submitted. Having these data allow us to plot various combinations of logging runs at scales which show us what we think we need to see.

5 Interpretation

Each of the three testing methods is interpreted individually.

5.1 The slug tracking records are evaluated by:

1. Reviewing the statistical check performed before testing began to check the sensitivity of the log display, check to be sure the scaling used for the logging is the same as was used for the statistical check;
2. Checking the deflection caused by the slug within the tubing or casing. It should be at least 50 times greater than that caused by lithological background;
3. Checking to see if a slug split occurred at the base of the tubing or casing. Identify any increases of radioactivity along the well bore above the base of the tubing or casing;
4. Evaluating the slug split for upward movement. Turbulence at the base of the tubing often causes some tracer to remain. If only a slow dissipation of the resulting hot spot, with no upward movement, is observed, the split has no significance;
5. If the tubing extends below the casing, upward movement to the base of the casing commonly occurs, this also has no environmental significance;
6. If movement above the base of the casing occurs, its extent must be very carefully determined and recorded. It is not uncommon or of concern if there is some limited movement, particularly where the base of the casing is within a porous, permeable interval. The extent of upward movement should be compared with previous measurements to confirm that the cement seal is not deteriorating.

5.2 The stationary tests are evaluated by:

1. Checking the strength of the slug, often the detector cannot react quickly enough to measure the entire distance of the deflection. The deflection should appear sharp if the total deflection is not measured;
2. Checking the record from the lower detector to see if any increase occurred after the initial passage of the slug;
3. If a second increase in radiation was detected, check the record from the upper detector (above the ejector) to check whether an increase occurred at that detector before the detection of the slug by the lower detector, if so, the detection may be due to an extraneous slug, previously ejected, moving downward past the tool;
4. If no increase in radiation is detected by the upper detector, then the tracer exited the well bore between the lower detector and the upper detector. The maximum upward movement identified through this test is the elevation of the upper detector;
5. If an increase in gamma ray radiation is detected by the upper detector after the detection by the lower detector, the tool should have been moved upward so that the slug had the

opportunity to pass both of the detectors again. If so, repeat steps 2, 3, and 4 until the maximum upward extent of movement of the tracer is established. This depth should be recorded and compared with that for the slug tracking and tests conducted in previous years;

5.3 To evaluate the logs run before and after all other tests are performed:

1. The logs should be printed overlain on the same depth scale. If not, on a light table, light box or back-lighted window, overlay the initial log above the final log. Focus on the interval just above the top of the injection interval;
2.
3. After matching depth and/or collar log features, check to be sure that the gamma ray traces overlay. If they do not, shift one log to the left or right until they generally overlay;
4. Identify regions in which the final log indicates apparent increased radiation. If the magnitude of the increased radiation is greater than the statistical variation, then radioactive tracer material has probably adhered to either the well construction materials or the borehole walls where the waste exited the well bore; and
5. Try to relate all instances of increased radiation above the casing shoe to the results of the previous testing. If unexplained occurrences persist, the results of a recent part 2 MI test should be carefully reviewed to see if upward movement is indicated.

5.4 The result of the testing should be determination of a depth above which no upward movement occurs. The result should be at or below the casing shoe. If it is above the casing shoe, the extent should be tracked and significance determined.

ATTACHMENT 9
CEMENTING RECORDS

1 Basis

A very small span of sound cement surrounding the casing will prevent movement between the well bore and the casing or between casings.

The use of cementing records as a demonstration of part 2 of MI is limited to all Class II wells and those Class III wells in which the nature of the construction precludes the use of temperature or noise logs. The cementing records must indicate that cement is present along the well bore between the injection zone and the base of the lowermost USDW.

2 Advantages and Disadvantages

Advantages:

1. Usually based on existing information
2. A one-time demonstration

Disadvantages:

1. This is an indirect demonstration. The presence of cement does not assure us that it is sound
2. If paper records are not available, they cannot be reconstructed
3. Either the CBL or CET requires that the well bore be water filled to the upper limit of the logged interval

3 Equipment and Forms

1. Forms of Cementing Records

   Cementing records include any acceptable records containing information which allows the calculation of cement placement behind the casings of wells. Cementing records may include

cement bond logs, cement evaluation logs, and temperature logs which give evidence of the location and/or quality of cement along well bores. The most reliable cementing records are job reports from cementing companies, but any records of construction containing information about the placement of cement may be acceptable. Either the original or copies of t hese cementing records must be submitted.

2. Cement Bond and Cement Evaluation Logs

   Cement bond logs (CBLs) use sonic attenuation and travel time to determine whether casing is cemented or free. The more cement which is bonded to casing, the greater will be the attenuation of sounds transmitted along the casing. The Cement Evaluation Tool (CET) operates on a principle similar to the CBL except that the tool uses many sound transmitters and receptors to evaluate the cement in various sectors of the well bore. Instead of an average bond index accounting for the entire circumference of the well bore, the log can identify poor bonding in single 60o segments. This increases the ability to confirm the presence of channels tremendously.

   The logs should include a gamma ray curve, casing collar log, acoustic amplitude and travel time curves, and CBLs should include an acoustic variable density log (VDL). The left hand track should contain the gamma ray and casing collar log. The right hand tracks should contain the acoustic amplitude and travel-time curves in track 2 and the acoustic VDL in track 3. CETs include a graphical depiction of the cemented area of the well bore in track 3. If available, a shop calibration record should be attached. The surface pressure under which the log was run should be noted on the log form.

   In new wells, the cement should be allowed to set for at least 72 hours before logging.

4 Procedures for Recording the Cement Bond Log (CBL) or Logs made Using Cement Evaluation Tool (CET)

1. Centralize the tool. Be sure that the part of the hole to be logged is liquid filled. Calibrate the tool;
2. Record the amplitude and travel time measured by the short- spaced receiver in the fixed gate mode;
3. Run the CBL over the entire cemented length of the casing and through at least two joints of the uncemented portion, if any;
4. Check the travel time. If intervals are found having four microseconds less than travel time in free pipe, check the tool centralization and relog the well if necessary;
5. If the log indicates poor bond, the log can be run under pressure to eliminate any micro-annulus effect. The pressure used should be minimal to prevent enlargement of the micro-annulus. Often reproduction of the pressure used during cement setting is sufficient. For Class I wells (although cement logs are occasionally required at Class I sites, they are not a demonstration of part 2 of MI) pressurizing to the normal annulus pressure may be sufficient to eliminate the micro- annulus; and
6. Check the tool calibration. If significant tool drift has occurred, relog the well with the back-up tool.

5 Interpretation

1. Interpretation of records

   Most cement records document the volume of cement emplaced between the casing and the well bore. For demonstrations of MI for Class II wells, the records must indicate that cement was emplaced at locations which will prevent upward movement from the injection zone. For demonstrations of MI for Class III wells, the records must indicate that cement was emplaced at locations which will prevent upward movement from the injection zone and into or between USDWs.

2. Interpretation of CBLs

   The log is examined to identify the location of cement along the casing. Only a few feet of sound cement are required to prevent flow along the well bore, but in most cases making judgements about the adequacy of a few feet of cement will not be required because there will be more than 10 feet of cement indicated to be sound, or there will be no indications of

sound cement in critical areas. If an initial cement bond log does not indicate the presence of cement, often a second log will be run with pressure on the casing. This may show cement while the earlier log does not. In this case, a microannulus has developed due to past expansion of the casing while it was pressurized during operations or testing. It is sometimes necessary to pressurize the casing above the highest pressure to which it has been subjected. The presence of a microannulus does not indicate a lack of part 2 of MI. Microannuli are very minute. By definition, while they may allow the passage of gas but not liquids.

If there is a question about the adequacy of cement to prevent the movement of liquids into USDWs, then one of the previously described logs, pre-approved by Region 5, should be utilized to demonstrate MI.

ATTACHMENT 10
RADIOACTIVE TRACER SURVEYS FOR
THE INTEGRITY OF CEMENT AT THE TOP OF THE INJECTION INTERVAL

1 Basis

The basis of the use of the RTS for confirming the integrity of the cement at the top of the injection interval is identical to that of demonstrating part 2 of MI. In fact, if there are no aquifers above the injection interval from which the waters might degrade any USDW, the demonstration of cement integrity becomes a demonstration of part 2 of MI.

2 Advantages and Disadvantages

This test is required annually for Class I wells which are used to inject hazardous waste; there is no alternative test. The logs used to demonstrate part 2 of MI may also make a similar demonstration, but such a demonstration cannot be substituted for the RTS for this purpose. Because there is no alternative, and the advantages and disadvantages of the log have been previously listed in Attachment 8, they are not listed here.

3 Equipment and Forms

These are identical to the equipment and forms listed in Attachment 3 for the RTS.

4 Procedures

The procedures for using the RTS to confirm the integrity of cement are identical to those used for the demonstration of part 2 of MI.

5 Interpretation

The interpretation of the RTS used for confirming the integrity of cement is similar to that for demonstrating part 2. If any upward movement is observed, it becomes critical to determine the exact amount of upward movement. The upper limits of upward movement are recorded and compared from year to year to check for any increase.

EPA Region 6

UIC PRESSURE FALLOFF TESTING GUIDELINE

Third Revision
August 8, 2002

1.0 Background

The Hazardous and Solid Waste Amendments of 1984 to the Resource Conservation and Recovery Act mandated prohibitions on the land disposal of hazardous waste. These prohibitions are known as the land disposal restrictions and EPA promulgated regulations to implement these requirements for injection wells on July 26, 1988. The land disposal restrictions for injection wells are codified in 40 CFR Part 148. In addition to specifying the effective dates of the restrictions on injection of specific hazardous wastes, these regulations outline the requirements for obtaining an exemption to the restrictions.

Facilities that have received an exemption to the land disposal restrictions under 40 CFR Part 148 have demonstrated that, to a reasonable degree of certainty, there will be no migration of hazardous constituents from the injection zone for as long as the waste remains hazardous. As part of this approval, facilities are required by Region 6 to meet approval conditions including annual monitoring in accordance with 40 CFR 148.20(d)(2).

Region 6 has adopted the 40 CFR 146.68(e)(1) requirements for monitoring Class 1 hazardous waste disposal wells. Under 40 CFR 146.68(e)(1), operators are required annually to monitor the pressure buildup in the injection zone, including at a minimum, a shut down of the well for a time sufficient to conduct a valid observation of the pressure falloff curve.

A falloff test is a pressure transient test that consists of shutting in an injection well and measuring the pressure falloff. The falloff period is a replay of the injection preceding it; consequently, it is impacted by the magnitude, length, and rate fluctuations of the injection period. Falloff testing analysis provides transmissibility, skin factor, and well flowing and static pressures. All of these parameters are critical for evaluation of technical adequacy of no migration demonstrations and UIC permits.

2.0 Purpose of Guideline

This guideline has been developed by the Region 6 office of the Evironmental Protection Agency (EPA) to assist operators in planning and conducting the falloff test and preparing the annual monitoring report. Typically, this report should consist of a falloff test and a comparison of the reservoir parameters derived from the test with those of the petition demonstration. Falloff tests provide reservoir pressure data and characterize both the injection interval reservoir and the completion condition of the injection well. Both the reservoir parameters and pressure data are

necessary for no migration and UIC permit demonstrations. Additionally, a valid falloff test is a requirement of a no migration petition condition as well as a monitoring requirement under 40 CFR Part 146 for all Class I injection wells. For no migration purposes, the annual report is viewed not as an enforcement tool, but as an annual confirmation that the petition demonstration continues to be valid.

The main body of this guideline contains general information that pertains to the majority of the facilities impacted. Because each site is unique, one guideline cannot be written to encompass all situations. A more detailed discussion of many topics and equations is included in the attached Appendix.

The ultimate responsibility of conducting a valid falloff test is the task of the operator. Operators should QA/QC the pressure data and test results to confirm that the results "make sense" prior to submission of the report to the EPA for review.

3.0 Timing of Falloff Tests and Report Submission

Falloff tests must be conducted within one year from the date of the original petition approval and annually thereafter. The time interval for each test should not be less than 9 months or greater than 15 months from the previous test. This will ensure that the tests will be performed at relatively even intervals throughout the duration of the petition approval period. Operators can, at their discretion, plan these tests to coincide with the performance of their annual state MIT requirements as long as the time requirements are met. The falloff testing report should be submitted no later than 60 days following the test. Failure to submit a falloff test report will be considered a violation of the applicable petition condition and may result in an enforcement action. Any exceptions should be approved by EPA prior to conducting the test.

4.0 Falloff Test Report Requirements

In general, the report to EPA should provide general information and an overview of the falloff test, an analysis of the pressure data obtained during the test, a summary of the test results, and a comparison of the results with the parameters used in the no migration demonstration. Some of the following operator and well data will not change so once acquired, it can be copied and submitted with each annual report. The falloff test report should include the following information:

1. Company name and address
2. Test well name and location
3. The name and phone number of the facility contact person. The contractor contact may be included if approved by the facility <u>in addition</u> to a facility contact person.

4. A photocopy of an openhole log (SP or Gamma Ray) through the injection interval illustrating the type of formation and thickness of the injection interval. The entire log is not necessary.
5. Well schematic showing the current wellbore configuration and completion information:
   - Wellbore radius
   - Completed interval depths
   - Type of completion (perforated, screen and gravel packed, openhole)
6. Depth of fill depth and date tagged.
7. Offset well information:
   - Distance between the test well and offset well(s) completed in the same interval or involved in an interference test
   - Simple illustration of locations of the injection and offset wells
8. Chronological listing of daily testing activities.
9. Electronic submission of the raw data (time, pressure, and temperature) from all pressure gauges utilized on a floppy disk or CD-ROM. A READ.ME file or the disk label should list all files included and any necessary explanations of the data. A separate file containing any edited data used in the analysis can be submitted as an additional file.
10. Tabular summary of the injection rate or rates preceding the falloff test. At a minimum, rate information for 48 hours prior to the falloff or for a time equal to twice the time of the falloff test is recommended. If the rates varied and the rate information is greater than 10 entries, the rate data should be submitted electronically as well as a hard copy of the rates for the report. Including a rate vs time plot is also a good way to illustrate the magnitude and number of rate changes prior to the falloff test.
11. Rate information from any offset wells completed in the same interval. At a minimum, the injection rate data for the 48 hours preceding the falloff test should be included in a tabular and electronic format. Adding a rate vs time plot is also helpful to illustrate the rate changes.
12. Hard copy of the time and pressure data analyzed in the report.
13. Pressure gauge information: (See Appendix, page A-1 for more information on pressure gauges)
   - List all the gauges utilized to test the well
   - Depth of each gauge
   - Manufacturer and type of gauge. Include the full range of the gauge.
   - Resolution and accuracy of the gauge as a % of full range.
   - Calibration certificate and manufacturer's recommended frequency of calibration
14. General test information:
   - Date of the test
   - Time synchronization: A specific time and date should be synchronized to an equivalent time in each pressure file submitted. Time synchronization should also be provided for the rate(s) of the test well and any offset wells.
   - Location of the shut-in valve (e.g., note if at the wellhead or number of feet from the wellhead)

15. Reservoir parameters (determination):
    - Formation fluid viscosity, μ_f cp (direct measurement or correlation)
    - Porosity, ϕ fraction (well log correlation or core data)
    - Total compressibility, c_t psi^{-1} (correlations, core measurement, or well test)
    - Formation volume factor, rvb/stb (correlations, usually assumed 1 for water)
    - Initial formation reservoir pressure - See Appendix, page A-1
    - Date reservoir pressure was last stabilized (injection history)
    - Justified interval thickness, h ft - See Appendix, page A-15
16. Waste plume:
    - Cumulative injection volume into the completed interval
    - Calculated radial distance to the waste front, r_{waste} ft
    - Average historical waste fluid viscosity, if used in the analysis, μ_{waste} cp
17. Injection period:
    - Time of injection period
    - Type of test fluid
    - Type of pump used for the test (e.g., plant or pump truck)
    - Type of rate meter used
    - Final injection pressure and temperature
18. Falloff period:
    - Total shut-in time, expressed in real time and Δt, elapsed time
    - Final shut-in pressure and temperature
    - Time well went on vacuum, if applicable
19. Pressure gradient:
    - Gradient stops - for depth correction
20. Calculated test data: include all equations used and the parameter values assigned for each variable within the report
    - Radius of investigation, r_i ft
    - Slope or slopes from the semilog plot
    - Transmissibility, kh/μ: md-ft/cp
    - Permeability (range based on values of h)
    - Calculation of skin, s
    - Calculation of skin pressure drop, ΔP_{skin}
    - Discussion and justification of any reservoir or outer boundary models used to simulate the test
    - Explanation for any pressure or temperature anomaly if observed
21. Graphs:
    - Cartesian plot: pressure and temperature vs. time
    - Log-log diagnostic plot: pressure and semilog derivative curves. Radial flow regime should be identified on the plot
    - Semilog and expanded semilog plots: radial flow regime indicated and the semilog straight line drawn
    - Injection rate(s) vs time: test well and offset wells (not a circular or strip chart)
22. A comparison of all parameters with those used in the petition demonstration, including references where the parameters can be found in the petition.

23. A copy of the latest radioactive tracer run to fulfill the annual mechanical integrity testing requirement for the State and a brief discussion of the results.
24. Compliance with any unusual petition approval conditions such as the submission of an annual flow profile survey. These additional conditions may be addressed either in the annual falloff testing report or in an accompanying document.

5.0 Planning

The radial flow portion of the test is the basis for all pressure transient calculations. Therefore the injectivity and falloff portions of the test should be designed not only to reach radial flow, but to sustain a time frame sufficient for analysis of the radial flow period.

General Operational Concerns

Successful well testing involves the consideration of many factors, most of which are within the operator's control. Some considerations in the planning of a test include:

- Adequate storage for the waste should be ensured for the duration of the test
- Offset wells completed in the same formation as the test well should be shut-in, or at a minimum, provisions should be made to maintain a constant injection rate prior to and during the test
- Install a crown valve on the well prior to starting the test so the well does not have to be shut-in to install a pressure gauge
- The location of the shut-in valve on the well should be at or near the wellhead to minimize the wellbore storage period
- The condition of the well, junk in the hole, wellbore fill or the degree of wellbore damage (as measured by skin) may impact the length of time the well must be shut-in for a valid falloff test. This is especially critical for wells completed in relatively low transmissibility reservoirs or wells that have large skin factors.
- Cleaning out the well and acidizing may reduce the wellbore storage period and therefore the shut-in time of the well
- Accurate recordkeeping of injection rates is critical including a mechanism to synchronize times reported for injection rate and pressure data. The elapsed time format usually reported for pressure data does not allow an easy synchronization with real time rate information. Time synchronization of the data is especially critical when the analysis includes the consideration of injection from more than one well.
- Any unorthodox testing procedure, or any testing of a well with known or anticipated problems, should be discussed with EPA staff prior to performing the test.
- Other pressure transient tests may be used in conjunction or in place of a falloff test in some situations. For example, if surface pressure measurements must be used because of a corrosive wastestream and the well will go on vacuum following shut-in, a multi-rate test may be used so that a positive surface pressure is maintained at the well.

- If more than one well is completed into the same reservoir, operators are encouraged to send at least two pulses to the test well by way of rate changes in the offset well following the falloff test. These pulses will demonstrate communication between the wells and, if maintained for sufficient duration, they can be analyzed as an interference test to obtain interwell reservoir parameters.

Site Specific Pretest Planning

1. Determine the time needed to reach radial flow during the injectivity and falloff portions of the test:
   - Review previous welltests, if available
   - Simulate the test using measured or estimated reservoir and well completion parameters
   - Calculate the time to the beginning of radial flow using the empirically-based equations provided in the Appendix. The equations are different for the injectivity and falloff portions of the test with the skin factor influencing the falloff more than the injection period. (See Appendix, page A-4 for equations)
   - Allow adequate time beyond the beginning of radial flow to observe radial flow so that a well developed semilog straight line occurs. A good rule of thumb is 3 to 5 times the time to reach radial flow to provide adequate radial flow data for analysis.

2. Adequate and consistent injection fluid should be available so that the injection rate into the test well can be held constant prior to the falloff. This rate should be high enough to produce a measurable falloff at the test well given the resolution of the pressure gauge selected. The viscosity of the fluid should be consistent. Any mobility issues (k/:) should be identified and addressed in the analysis if necessary.

3. Bottomhole pressure measurements are usually superior to surface pressure measurements because bottomhole measurements tend to be less noisy. Surface pressure measurements can be used if positive pressure is maintained at the surface throughout the falloff portion of the test. The surface pressure gauge should be located at the wellhead. A surface pressure gauge may also serve as a backup to a downhole gauge and provide a monitoring tool for tracking the test progress. Surface gauge data can be plotted during the falloff in a log-log plot format with the pressure derivative function to determine if the test has reached radial flow and can be terminated. Note: Surface pressure measurements are not adequate if the well goes on a vacuum during the test. (See Appendix, page A-2 for additional information concerning pressure gauge selection.)

4. Use two pressure gauges during the test with one gauge serving as a backup, or for verification in cases of questionable data quality. The two gauges do not need to be the same type. (See Appendix, page A-1 for additional information concerning pressure gauges.)

6.0 Conducting the Falloff Test

1. Tag and record the depth to any fill in the test well

2. Simplify the pressure transients in the reservoir
   - C Maintain a constant injection rate in the test well prior to shut-in. This injection rate should be high enough and maintained for a sufficient duration to produce a measurable pressure transient that will result in a valid falloff test.
   - C Offset wells should be shut-in prior to and during the test. If shut-in is not feasible, a constant injection rate should be recorded and maintained during the test and then accounted for in the analysis.
   - C Do not shut-in two wells simultaneously or change the rate in an offset well during the test.

3. The test well should be shut-in at the wellhead in order to minimize wellbore storage and afterflow. (See Appendix, page A-3 for additional information.)

4. Maintain accurate rate records for the test well and any offset wells completed in the same injection interval.

5. Measure and record the viscosity of the injectate periodically during the injectivity portion of the test to confirm the consistency of the test fluid.

7.0 Evaluation of the Falloff Test

1. Prepare a Cartesian plot of the pressure and temperature versus real time or elapsed time.
   - C Confirm pressure stabilization prior to shut-in of the test well
   - C Look for anomalous data, pressure drop at the end of the test, determine if pressure drop is within the gauge resolution

2. Prepare a log-log diagnostic plot of the pressure and semilog derivative. Identify the flow regimes present in the welltest. (See Appendix, page A-6 for additional information.)
   - C Use the appropriate time function depending on the length of the injection period and variation in the injection rate preceding the falloff (See Appendix, page A-10 for details on time functions.)
   - C Mark the various flow regimes - particularly the radial flow period
   - C Include the derivative of other plots, if appropriate (e.g., square root of time for linear flow)
   - C If there is no radial flow period, attempt to type curve match the data

3. Prepare a semilog plot.
   - Use the appropriate time function depending on the length of injection period and injection rate preceding the falloff
   - Draw the semilog straight line through the radial flow portion of the plot and obtain the slope of the line
   - Calculate the transmissibility, kh/:
   - Calculate the skin factor, s, and skin pressure drop, ΔP_{skin}
   - Calculate the radius of investigation, r_i

4. Explain any anomalous results.

8.0 Comparison of Falloff Results to No Migration Petition Data

A comparison between the falloff test results and the parameters used in the no migration petition demonstration should be made. Specifically, the following should be demonstrated:

- Both the flowing and static bottom hole pressures measured during the test should be corrected for skin and be at or below those which were predicted to occur by the pressure buildup model in the approvided no migration petition for the same point in time. (See Appendix, page A-13)

- It should be shown that the (kh/:) parameter group calculated from the current falloff data is the same or greater than that employed in the pressure buildup modeling.

APPENDIX

Initial Formation Reservoir Pressure from Falloff Testing

For use in the no migration demonstration pressure buildup modeling:

- Some predictive models calculate a pressure buildup while other models calculate a specific pressure based on an initial reservoir pressure assigned to the model. No wellbore skin should be assumed in the demonstration. Historical falloff flowing pressure data used for comparison with model results should be corrected for skin effects
- The initial pressure should represent the initial reservoir pressure prior to initiation of injection in the model.
- Direct bottomhole static measurements are best. If no measurements are available, or are questionable, attempt to correct static surface pressures to bottomhole conditions. Use site specific information if available. Alternatively, the facility can reference a technical paper that may discuss the initial pressure of the injection interval at another location in the same area or an initial static pressure measurement from an offset injection well.
- Review historical measured static pressures. The initial reservoir pressure should be lower than the measured static pressures following injection at the well.

For use in Cone of Influence (COI) calculations in both no migration demonstrations and UIC permits:

- P^* is the false extrapolated pressure obtained from the semilog straight line at a time of 1 hour and is often used as the average reservoir pressure
- P^* is only applicable for a new well in an infinite acting reservoir
- EPA Region 6 does not recommend using P^* for the average reservoir pressure. For long injection periods, P^* will differ significantly from $\overline{P}$, the average reservoir pressure
- Use the final shut-in pressure, if the well reaches radial flow, for the cone of influence calculation

Pressure Gauge Usage and Selection

<u>Usage</u>

- EPA recommends that two gauges be used during the test with one gauge serving as a backup.
- As a general rule, downhole pressure measurements are less noisy and are preferred. Surface pressure measurements can be employed if positive pressure is maintained at the surface throughout the test. Surface gauges are insufficient if the well goes on a vacuum.
- Surface pressure gauges may be impacted by the fluctuations in ambient temperature that can occur over the course of a normal day. If unchecked, this aspect of these gauges can result in erroneous pressure readings. Insulating the gauges appears to be an effective countermeasure for temperature fluctuations in many instances.

- A surface or bottomhole surface readout gauge (SRO) allows tracking of pressures in real time. Analysis of this data can be performed in the field to confirm that the well has reached radial flow prior to ending the test.
- The derivative function plotted on the log-log plot amplifies noise in the data, so the use of a good pressure recording device is critical for application of this curve.
- Mechanical gauges should be calibrated before and after each test using a dead weight tester.
- Electronic gauges should also be calibrated according to the manufacturer's recommendations. The manufacturer's recommended frequency of calibration, and a copy of the gauge calibration certificate should be provided with the falloff testing report demonstrating this practice has been followed.

Selection

- The pressures must remain within the range of the pressure gauge. The larger percent of the gauge range utilized in the test, the better. Typical pressure gauge limits are 2000, 5000, and 10000 psi. Note that gauge accuracy and resolution are typically a function of percent of the full gauge range.
- Electronic downhole gauges generally offer much better resolution and sensitivity than a mechanical gauge but cost more. Additionally, the electronic gauge can generally run for a longer period of time, be programmed to measure pressure more frequently at various intervals for improved data density, and store data in digital form.
- Resolution of the pressure gauge must be sufficient to measure small pressure changes at the end of the test.
- The type of wastestream injected may prevent the use of a downhole gauge unless brine from offsite is brought in and used for the test. This may be cost prohibitive.

Test Design

General Operational Considerations

- The injection period controls what is seen on the falloff since the falloff is replay of the injection period. Therefore, the injection period must reach radial flow prior to shut-in of the well in order for the falloff test to reach radial flow

- Ideally to determine the optimal lengths of the injection and falloff periods, the test should be simulated using measured or estimated reservoir parameters. Alternatively, injection and falloff period lengths can be estimated from empirical equations using assumed reservoir and well parameters.

- The injection rate dictates the pressure buildup at the injection well. The pressure buildup from injection must be sufficient so that the pressure change during radial flow, usually occurring toward the end of the test, is large enough to measure with the pressure gauge selected.

- Waste storage and other operational issues require preplanning and need to be addressed prior to the test date. If brine must be brought in for the injection portion of the test, operators should insure that the fluid injected has a consistent viscosity and that there is adequate fluid available to obtain a valid falloff test. The use of the wastestream as the injection fluid affords several distinct advantages:
  1. Brine does not have to be purchased or stored prior to use.
  2. Onsite waste storage tanks may be used.
  3. Plant wastestreams are generally consistent, i.e., no viscosity variations

- Rate changes cause pressure transients in the reservoir. Constant rate injection in the test well and any offset wells completed in the same reservoir are critical to simplify the pressure transients in the reservoir. Any significant injection rate fluctuations at the test well or offsets must be recorded and accounted for in the analysis using superposition.

- Unless an injectivity test is to be conducted, shutting in the well for an extend period of time prior to conducting the falloff test reduces the pressure buildup in the reservoir and is not recommended.

- Prior to conducting a test, a crown valve should be installed on the wellhead to allow the pressure gauge to be installed and lowered into the well without any interruption of the injection rate.

- The wellbore schematic should be reviewed for possible obstructions located in the well that may prevent the use or affect the setting depth of a downhole pressure gauge. The fill depth in the well should also be reported. The fill depth may not only impact the depth of the gauge, but usually prolongs the wellbore storage period and depending on the type of fill, may limit the interval thickness by isolating some of the injection intervals. A wellbore cleanout or stimulation may be needed prior to conducting the test for the test to reach radial flow and obtain valid results.

- The location of the shut-in valve can impact the duration of the wellbore storage period. The shut-in valve should be located near the wellhead. Afterflow into the wellbore prolongs the wellbore storage period. The injection pipeline leading to the well can act as an extension to the well if the shut-in valve is not located near the wellhead. Operators should report the location of the shut-in valve and its distance from the wellhead, in the test report.

- The area geology should be reviewed prior to conducting the test to determine the thickness and type of formation being tested along with any geological features such as natural fractures, a fault, or a pinchout that should be anticipated to impact the test.

Wellbore and Reservoir Data Needed to Simulate or Analyze the Falloff Test

- Wellbore radius, r_w - from wellbore schematic
- Net thickness, h - See Appendix, page A-15
- Porosity, N - log or core data
- Viscosity of formation fluid, μ_f - direct measurement or correlations
- Viscosity of waste, μ_{waste} - direct measurement or correlations
- Total system compressibility, c_t - correlations, core measurement, or well test
- Permeability, k - previous welltests or core data
- Specific gravity of injection fluid, s.g. - direct measurement
- Injection rate, q - direct measurement

Design Calculations

When simulation software is unavailable the test periods can be estimated from empirical equations. The following are set of steps to calculate the time to reach radial flow from empirically-derived equations:

1. Estimate the wellbore storage coefficient, C (bbl/psi). There are two equations to calculate the wellbore storage coefficient depending on if the well remains fluid filled (positive surface pressure) or if the well goes on a vacuum (falling fluid level in the well):
   a. Well remains fluid filled:

      $C = V_w \cdot c_{waste}$

      where, V_w is the total wellbore volume, bbls

      c_{waste} is the compressibility of the injectate, psi^{-1}

   b. Well goes on a vacuum:

      $$C = \frac{V_u}{\frac{r \cdot g}{144 \cdot g_c}}$$

      where, V_u is the wellbore volume per unit length, bbls/ft

      D is the injectate density, psi/ft

      g and g_c are gravitational constants

2. Calculate the time to reach radial flow for both the injection and falloff periods. Two different empirically-derived equations are used to calculate the time to reach radial flow, $t_{radial\ flow}$, for the injectivity and falloff periods:
   a. Injectivity period:

      $$t_{radial\ flow} > \frac{(200000 + 12000s) \cdot C}{\frac{k \cdot h}{m}} \quad hours$$

   b. Falloff period:

      $$t_{radial\ flow} > \frac{170000 \cdot C \cdot e^{0.14 \cdot s}}{\frac{k \cdot h}{m}} \quad hours$$

   The wellbore storage coefficient is assumed to be the same for both the injectivity and falloff periods. The skin factor, s, influences the falloff more than the injection period.

Use these equations with caution, as they tend to fall apart for a well with a large permeability or a high skin factor. Also remember, the welltest should not only reach radial flow, but also sustain radial flow for a timeframe sufficient for analysis of the radial flow period. As a rule of thumb, a timeframe sufficient for analysis is 3 to 5 times the time needed to reach radial flow.

3. As an alternative to steps 1 and 2, to look a specific distance "L" into the reservoir and possibly confirm the absence or existence of a boundary, the following equation can be used to estimate the time to reach that distance:

$$t_{boundary} = \frac{948 \cdot f \cdot m \cdot c_t \cdot L_{boundary}}{k} \quad hours$$

where, $L_{boundary}$ = feet to boundary
$t_{boundary}$ = time to boundary, hrs

Again, this is the time to reach a distance "L" in the reservoir. Additional test time is required to observe a fully developed boundary past the time needed to just reach the boundary. As a rule of thumb, to see a fully developed boundary on a log-log plot, allow at least 5 times the time to reach it. Additionally, for a boundary to show up on the falloff, it must first be encountered during the injection period.

4. Calculate the expected slope of the semilog plot during radial flow to see if gauge resolution will be adequate using the following equation:

$$m_{semi\log} = \frac{162.6 \cdot q \cdot B}{\frac{k \cdot h}{m}}$$

where, q = the injection rate preceding the falloff test, bpd
B = formation volume factor for water, rvb/stb (usually assumed to be 1)

<u>Considerations for Offset Wells Completed in the Same Interval</u>

Rate fluctuations in offset wells create additional pressure transients in the reservoir and complicate the analysis. Always try to simplify the pressure transients in the reservoir. Do not simultaneously shut-in an offset well and the test well. The following items are key considerations in dealing with the impact of offset wells on a falloff test:

- Shut-in all offset wells prior to the test
- If shutting in offset wells is not feasible, maintain a constant injection rate prior to and during the test
- Obtain accurate injection records of offset injection prior to and during the test
- At least one of the real time points corresponding to an injection rate in an offset well should be synchronized to a specific time relating to the test well

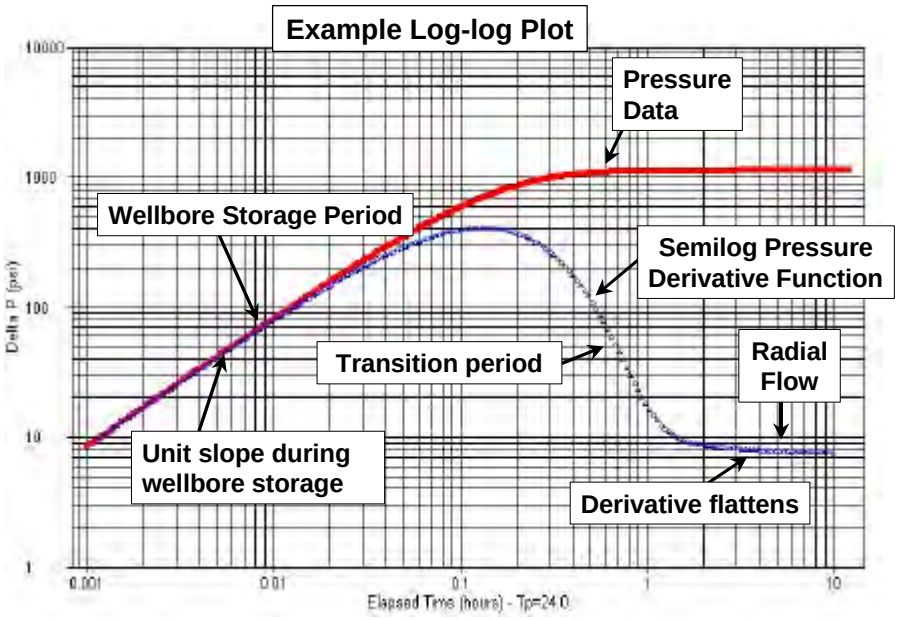
- Following the falloff test in the test well, send at least two pulses from the offset well to the test well by fluctuating the rate in the offset well. The pressure pulses can confirm communication between the wells and can be simulated in the analysis if observed at the test well. The pulses can also be analyzed as an interference test using an Ei type curve.
- If time permits, conduct an interference test to allow evaluation of the reservoir without the wellbore effects observed during a falloff test.

Falloff Test Analysis

In performing a falloff test analysis, a series of plots and calculations should be prepared to QA/QC the test, identify flow regimes, and determine well completion and reservoir parameters. Individual plots, flow regime signatures, and calculations are discussed in the following sections.

Cartesian Plot

- The pressure data prior to shut-in of the well should be reviewed on a Cartesian plot to confirm pressure stabilization prior to the test. A well that has reached radial flow during the injectivity portion of the test should have a consistent injection pressure.



- A Cartesian plot of the pressure and temperature versus real time or elapsed time should be the first plot made from the falloff test data. Late time pressure data should be expanded to determine the pressure drop occurring during this portion of the test. The pressure changes should be compared to the pressure gauges used to confirm adequate gauge resolution existed throughout the test. If the gauge resolution limit was reached, this timeframe should be identified to determine if radial flow was reached prior to reaching the resolution of the pressure gauge. Pressure data obtained after reaching the resolution of the gauge should be treated as suspect and may need to be discounted in the analysis.

- Falloff tests conducted in highly transmissive reservoirs may be more sensitive to the temperature compensation mechanism of the gauge because the pressure buildup response evaluated is smaller. Region 6 has observed cases in which large temperature anomalies were not properly compensated for by the pressure gauge, resulting in erroneous pressure data and an incorrect analysis. For this reason, the Cartesian plot of the temperature data should be reviewed. Any temperature anomalies should be noted to determine if they correspond to pressure anomalies.

- Include the injection rate(s) of the test well 48 hours prior to shut-in on the Cartesian plot to illustrate the consistency of the injection rate prior to shut-in and to determine the appropriate time function to use on the log-log and semilog plots. (See Appendix, page A10 for time function selection)

Log-log Diagnostic Plot

C Plot the pressure and semilog derivative versus time on a log-log diagnostic plot. Use the appropriate time function based on the rate history of the injection period preceding the falloff. (See Appendix, page A-10 for time function selection) The log-log plot is used to identify the flow regimes present in the welltest. An example log-log plot is shown below:

Identification of Test Flow Regimes

C Flow regimes are mathematical relationships between pressure, rate, and time. Flow regimes provide a visualization of what goes on in the reservoir. Individual flow regimes have characteristic slopes and a sequencing order on the log-log plot.

C Various flow regimes will be present during the falloff test, however, not all flow regimes are observed on every falloff test. The late time responses correlate to distances further from the test well. The critical flow regime is radial flow from which all analysis calculations are performed. During radial flow, the pressure responses recorded are representative of the reservoir, not the wellbore.

C The derivative function amplifies reservoir signatures by calculating a running slope of a designated plot. The derivative plot allows a more accurate determination of the radial flow portion of the test, in comparison with the old method of simply proceeding 1½ log cycles from the end of the unit slope line of the pressure curve.

C The derivative is usually based on the semilog plot, but it can also be calculated based on other plots such as a Cartesian plot, a square root of time plot, a quarter root of time plot, and the 1/square root of time plot. Each of these plots are used to identify specific flow

regimes. If the flow regime characterized by a specialized plot is present then when the derivative calculated from that plot is displayed on the log-log plot, it will appear as a "flat spot" during the portion of the falloff corresponding to the flow regime.

C Typical flow regimes observed on the log-log plot and their semilog derivative patterns are listed below:

Flow Regime	Semilog Derivative Pattern
Wellbore Storage	Unit slope
Radial Flow	Flat plateau
Linear Flow	Half slope
Bilinear Flow	Quarter slope
Partial Penetration	Negative half slope
Layering	Derivative trough
Dual Porosity	Derivative trough
Boundaries	Upswing followed by plateau
Constant Pressure	Sharp derivative plunge

Characteristics of Individual Test Flow Regimes

C Wellbore Storage:

1. Occurs during the early portion of the test and is caused by the well being shut-in at the surface instead of the sandface
2. Measured pressure responses are governed by well conditions and are not representative of reservoir behavior and are characterized by both the pressure and semilog derivative curves overlying a unit slope on the log-log plot
3. Wellbore skin or a low permeability reservoir results in a slower transfer of fluid from the well to the formation, extending the duration of the wellbore storage period
4. A wellbore storage dominated test is unanalyzable

C Radial Flow:

1. The pressure responses are from the reservoir, not the wellbore
2. The critical flow regime from which key reservoir parameters and completion conditions calculations are performed
3. Characterized by a flattening of the semilog plot derivative curve on the log-log plot and a straight line on the semilog plot

C Spherical Flow:

1. Identifies partial penetration of the injection interval at the wellbore
2. Characterized by the semilog derivative trending along a negative half slope on the log-log plot and a straight line on the 1/square root of time plot
3. The log-log plot derivative of the pressure vs 1/square root of time plot is flat

- Linear Flow
  1. May result from flow in a channel, parallel faults, or a highly conductive fracture
  2. Characterized by a half slope on both the log-log plot pressure and semilog derivative curves with the derivative curve approximately 1/3 of a log cycle lower than the pressure curve and a straight line on the square root of time plot.
  3. The log-log plot derivative of the pressure vs square root of time plot is flat

- Hydraulically Fractured Well
  1. Multiple flow regimes present including wellbore storage, fracture linear flow, bilinear flow, pseudo-linear flow, formation linear flow, and pseudo-radial flow
  2. Fracture linear flow is usually hidden by wellbore storage
  3. Bilinear flow results from simultaneous linear flows in the fracture and from the formation into the fracture, occurs in low conductivity fractures, and is characterized by a quarter slope on both the pressure and semilog derivative curves on the log-log plot and by a straight line on a pressure versus quarter root of time plot
  4. Formation linear flow is identified by a half slope on both the pressure and semilog derivative curves on the log-log plot and by a straight line on a pressure versus square root of time plot
  5. Psuedo-radial flow is analogous to radial flow in an unfractured well and is characterized by flattening of semilog derivative curve on the log-log plot and a straight line on a semilog pressure plot

- Naturally Fractured Rock
  1. The fracture system will be observed first on the falloff test followed by the total system consisting of the fractures and matrix.
  2. The falloff analysis is complex. The characteristics of the semilog derivative trough on the log-log plot indicate the level of communication between the fractures and the matrix rock.

- Layered Reservoir
  1. Analysis of a layered system is complex because of the different flow regimes, skin factors or boundaries that may be present in each layer.
  2. The falloff test objective is to get a total tranmissibility from the whole reservoir system.
  3. Typically described as commingled (2 intervals with vertical separation) or crossflow (2 intervals with hydraulic vertical communication)

<u>Semilog Plot</u>

- The semilog plot is a plot of the pressure versus the log of time. There are typically four different semilog plots used in pressure transient and falloff testing analysis. After plotting the appropriate semilog plot, a straight line should be drawn through the points located within the equivalent radial flow portion of the plot identified from the log-log plot.

- Each plot uses a different time function depending on the length and variation of the injection rate preceding the falloff. These plots can give different results for the same test, so it is important that the appropriate plot with the correct time function is used for the analysis. Determination of the appropriate time function is discussed below.

- The slope of the semilog straight line is then used to calculate the reservoir transmissibility - kh/:, the completion condition of the well via the skin factor - s, and also the radius of investigation - r_i of the test.

Determination of the Appropriate Time Function for the Semilog Plot

The following four different semilog plots are used in pressure transient analysis:

1. Miller Dyes Hutchinson (MDH) Plot
2. Horner Plot
3. Agarwal Equivalent Time Plot
4. Superposition Time Plot

These plots can give different results for the same test. Use of the appropriate plot with the correct time function is critical for the analysis.

- The MDH plot is a semilog plot of pressure versus)t, where)t is the elapsed shut-in time of the falloff.
    1. The MDH plot only applies to wells that reach psuedo-steady state during injection. Psuedo-steady state means the pressure response from the well has encountered all the boundaries around the well.
    2. The MDH plot is only applicable to injection wells with a *very* long injection period at a constant rate. This plot is not recommended for use by EPA Region 6.

- The Horner plot is a semilog plot of pressure versus $(t_p+)t)/)t$. The Horner plot is only used for a falloff preceded by a single constant rate injection period.
    1. The injection time, $t_p=V_p/q$ in hours, where V_p=injection volume since the last pressure equalization and q is the injection rate prior to shut-in for the falloff test. The injection volume is often taken as the cumulative injection since completion.
    2. The Horner plot can result in significant analysis error if the injection rate varies prior to the falloff.

- The Agarwal equivalent time plot is a semilog plot of the pressure versus Agarwal equivalent time, $)t_e$.
    1. The Agarwal equivalent time function is similar to the Horner plot, but scales the falloff to make it look like an injectivity test.
    2. It is used when the injection period is a short, constant rate compared to the length of the falloff period.
    3. The Agarwal equivalent time is defined as: $)t_e=\log(t_p\ )t)/(t_p+)t)$, where t_p is calculated the same as with the Horner plot.

C The superposition time function accounts for variable rate conditions preceding the falloff.
   1. It is the most rigorous of all the time functions and is usually calculated using welltest software.
   2. The use of the superposition time function requires the operator to accurately track the rate history. As a rule of thumb, at a minimum, the rate history for twice the length of the falloff test should be included in the analysis.

The determination of which time function is appropriate for the plotting the welltest on semilog and log-log plots depends on available rate information, injection period length, and software:

1. If there is not a rate history other than a single rate and cumulative injection, use a Horner time function
2. If the injection period is shorter than the falloff test and only a single rate is available, use the Agarwal equivalent time function
3. If you have a variable rate history use superposition when possible. As an alternative to superposition, use Agarwal equivalent time on the log-log plot to identify radial flow. The semilog plot can be plotted in either Horner or Agarwal time if radial flow is observed on the log-log plot.

<u>Parameter Calculations and Considerations</u>

C Transmissibility - The slope of the semilog straight line, m, is used to determine the transmissibility (kh/∶) parameter group from the following equation:

$$\frac{k \cdot h}{m} = \frac{162.6 \cdot q \cdot \mathrm{B}}{m}$$

where, q = injection rate, bpd (negative for injection)
B = formation volume factor, rvb/stb (Assumed to be 1 for formation fluid)
m = slope of the semilog straight line through the radial flow portion of the plot in psi/log cycle
k = permeability, md
h = thickness, ft (See Appendix, page A-15)
∶ = viscosity, cp

C The viscosity, ∶, is usually that of the formation fluid. However, if the waste plume size is massive, the radial flow portion of the test may remain within the waste plume. (See Appendix, page A-14)
   1. The waste and formation fluid viscosity values usually are similar, however, if the wastestream has a significant viscosity difference, the size of the waste plume and distance to the radial flow period should be calculated.
   2. The mobility, k/∶, differences between the fluids may be observed on the derivative curve.

C The permeability, k, can be obtained from the calculated transmissibility (kh/∶) by

substituting the appropriate thickness, h, and viscosity, :, values.

Skin Factor

C In theory, wellbore skin is treated as an infinitesimally thin sheath surrounding the wellbore, through which a pressure drop occurs due to either damage or stimulation. Industrial injection wells deal with a variety of waste streams that alter the near wellbore environment due to precipitation, fines migration, ion exchange, bacteriological processes, and other mechanisms. It is reasonable to expect that this alteration often exists as a zone surrounding the wellbore and not a skin. Therefore, at least in the case of industrial injection wells, the assumption that skin exists as a thin sheath is not always valid. This does not pose a serious problem to the correct interpretation of falloff testing except in the case of a large zone of alteration, or in the calculation of the flowing bottomhole pressure. The Region has seen instances in which large zones of alteration were suspected of being present.

C The skin factor is the measurement of the completion condition of the well. The skin factor is quantified by a positive value indicating a damaged completion and a negative value indicating a stimulated completion.

1. The magnitude of the positive value indicating a damaged completion is dictated by the transmissibility of the formation.
2. A negative value of -4 to -6 generally indicates a hydraulically fractured completion, whereas a negative value of -1 to -3 is typical of an acid stimulation in a sandstone reservoir.
3. The skin factor can be used to calculate the effective wellbore radius, r_{wa} also referred to the apparent wellbore radius. (See Appendix, page A-13)
4. The skin factor can also be used to correct the injection pressure for the effects of wellbore damage to get the actual reservoir pressure from the measured pressure.

C The skin factor is calculated from the following equation:

$$s = 1.1513\left[\frac{P_{1hr} - P_{wf}}{m} - \log\left(\frac{k \cdot t_p}{\left(t_p + 1\right) \cdot f \cdot m \cdot c_t \cdot r_w^2}\right) + 3.23\right]$$

where, s = skin factor, dimensionless

P_{1hr} = pressure intercept along the semilog straight line at a shut-in time of 1 hour, psi

P_{wf} = measured injection pressure prior to shut-in, psi

: = appropriate viscosity at reservoir conditions, cp (See Appendix, page A-14)

m = slope of the semilog straight line, psi/cycle

k = permeability, md

N = porosity, fraction

c_t = total compressibility, psi^{-1}

r_w = wellbore radius, feet

t_p = injection time, hours

Note that the term $t_p/(t_p + \Delta t)$, where Δt=1 hr, appears in the log term. This term is usually assumed to result in a negligible contribution and typically is taken as 1 for large t. However, for relatively short injection periods, as in the case of a drill stem test (DST), this term can be significant.

Radius of Investigation

- The radius of investigation, r_i, is the distance the pressure transient has moved into a formation following a rate change in a well.

- There are several equations that exist to calculate the radius of investigation. All the equations are square root equations based on cylindrical geometry, but each has its own coefficient that results in slightly different results, (See Oil and Gas Journal, Van Poollen, 1964).

- Use of the appropriate time is necessary to obtain a useful value of r_i. For a falloff time shorter than the injection period, use Agarwal equivalent time function, Δt_e, at the end of the falloff as the length of the injection period preceding the shut-in to calculate r_i.

- The following two equivalent equations for calculating r_i were taken from SPE Monograph 1, (Equation 11.2) and Well Testing by Lee (Equation 1.47), respectively:

$$r_i = \sqrt{0.00105\frac{k \cdot t}{f \cdot m \cdot c_t}} \equiv \sqrt{\frac{k \cdot t}{948 \cdot f \cdot m \cdot c_t}}$$

Effective Wellbore Radius

- The effective wellbore radius relates the wellbore radius and skin factor to show the effects of skin on wellbore size and consequently, injectivity.

- The effective wellbore radius is calculated from the following:

$$r_{wa} = r_w e^{-s}$$

- A negative skin will result in a larger effective wellbore radius and therefore a lower injection pressure.

Reservoir Injection Pressure Corrected for Skin Effects

- The pressure correction for wellbore skin effects, ΔP_{skin}, is calculated by the following:

$$\Delta P_{skin} = 0.868 \cdot m \cdot s$$

where, m = slope of the semilog straight line, psi/cycle
s = wellbore skin, dimensionless

- The adjusted injection pressure, P_{wfa} is calculated by subtracting the ΔP_{skin} from the measured injection pressure prior to shut-in, P_{wf}. This adjusted pressure is the calculated reservoir pressure prior to shutting in the well, Δt=0, and is determined by the following:

$$P_{wfa} = P_{wf} - \Delta P_{skin}$$

- From the previous equations, it can be seen that the adjusted bottomhole pressure is directly dependent on a single point, the last injection pressure recorded prior to shut-in. Therefore, an accurate recording of this pressure prior to shut-in is important. Anything that impacts the pressure response, e.g., rate change, near the shut-in of the well should be avoided.

Determination of the Appropriate Fluid Viscosity

- If the wastestream and formation fluid have similar viscosities, this process is not necessary.

- This is only needed in cases where the mobility ratios are extreme between the wastestream, $(k/\mu)_w$, and formation fluid, $(k/\mu)_f$. Depending on when the test reaches radial flow, these cases with extreme mobility differences could cause the derivative curve to change and level to another value. Eliminating alternative geologic causes, such as a sealing fault, multiple layers, dual porosity, etc., leads to the interpretation that this change may represent the boundary of the two fluid banks.

- First assume that the pressure transients were propagating through the formation fluid during the radial flow portion of the test, and then verify if this assumption is correct. This is generally a good strategy except for a few facilities with exceptionally long injection histories, and consequently, large waste plumes. The time for the pressure transient to exit the waste front is calculated. This time is then identified on both the log-log and semilog plots. The radial flow period is then compared to this time.

- The radial distance to the waste front can then be estimated volumetrically using the following equation:

$$r_{waste\ plume} = \sqrt{\frac{0.13368 \cdot V_{waste\ injected}}{p \cdot h \cdot f}}$$

where, $V_{waste\ injected}$ = cumulative waste injected into the completed interval, gal
$r_{waste\ plume}$ = estimated distance to waste front, ft
h = interval thickness, ft
ϕ = porosity, fraction

- The time necessary for a pressure transient to exit the waste front can be calculated using the following equation:

$$t_w = \frac{126.73 \cdot m_w \cdot c_t \cdot V_{waste\ injected}}{p \cdot k \cdot h}$$

where, t_w= time to exit waste front, hrs
$V_{waste\ injected}$ = cumulative waste injected into the completed interval, gal
h = interval thickness, ft

k = permeability, md

μ_w = viscosity of the historic waste plume at reservoir conditions, cp

c_t = total system compressibility, psi^{-1}

- The time should be plotted on both the log-log and semilog plots to see if this time corresponds to any changes in the derivative curve or semilog pressure plot. If the time estimated to exit the waste front occurs before the start of radial flow, the assumption that the pressure transients were propagating through the reservoir fluid during the radial flow period was correct. Therefore, the viscosity of the reservoir fluid is the appropriate viscosity to use in analyzing the well test. If not, the viscosity of the historic waste plume should be used in the calculations. If the mobility ratio is extreme between the wastestream and formation fluid, adequate information should be included in the report to verify the appropriate fluid viscosity was utilized in the analysis.

Reservoir Thickness

- The thickness used for determination of the permeability should be justified by the operator. The net thickness of the defined injection interval is not always appropriate.

- The permeability value is necessary for plume modeling, but the transmissibility value, kh/μ, can be used to calculate the pressure buildup in the reservoir without specifying values for each parameter value of k, h, and μ.

- Selecting an interval thickness is dependent on several factors such as whether or not the injection interval is composed of hydraulically isolated units or a single massive unit and wellbore conditions such as the depth to wellbore fill. When hydraulically isolated sands are present, it may be helpful to define the amount of injection entering each interval by conducting a flow profile survey. Temperature logs can also be reviewed to evaluate the intervals receiving fluid. Cross-sections may provide a quick look at the continuity of the injection interval around the injection well.

- A copy of a SP/Gamma Ray well log over the injection interval, the depth to any fill, and the log and interpretation of available flow profile surveys run should be submitted with the falloff test to verify the reservoir thickness value assumed for the permeability calculation.

Use of Computer Software

- To analyze falloff tests, operators are encouraged to use well testing software. Most software has type curve matching capabilities. This feature allows the simulation of the entire falloff test results to the acquired pressure data. This type of analysis is particularly useful in the recognition of boundaries, or unusual reservoir characteristics, such as dual porosity. It should be noted that type curve matching is not considered a substitute, but is a compliment to the analysis.

- All data should be submitted electronically with a label stating the name of the facility, the well number(s), and the date of the test(s). The label or READ.Me file should include

the names of all the files contained on the diskette, along with any necessary explanations of the information. The parameter units format (hh:mm:ss, hours, etc.) should be noted for the pressure file for synchronization to the submitted injection rate information. The file containing the gauge data analyzed in the report should be identified and consistent with the hard copy data included in the report. If the injection rate information for any well included in the analysis is greater than 10 entries, it should also be included electronically.

Common Sense Check

- After analyzing any test, always look at the results to see if they "make sense" based on the type of formation tested, known geology, previous test results, etc. Operators are ultimately responsible for conducting an analyzable test and the data submitted to the regulatory agency.

- If boundary conditions are observed on the test, review cross-sections or structure maps to confirm if the presence of a boundary is feasible. If so, the boundary should be considered in the AOR pressure buildup evaluation for the well.

- Anomalous data responses may be observed on the falloff test analysis. These data anomalies should be evaluated and explained. The analyst should investigate physical causes in addition to potential reservoir responses. These may include those relating to the well equipment, such as a leaking valve, or a channel, and those relating to the data acquisition hardware such as a faulty gauge. An anomalous response can often be traced to a brief, but significant rate change in either the test well or an offset well.

- Anomalous data trends have also been caused by such things as ambient temperature changes in surface gauges or a faulty pressure gauge. Explanations for data trends may be facilitated through an examination of the backup pressure gauge data, or the temperature data. It is often helpful to qualitatively examine the pressure and/or temperature channels from both gauges. The pressure data should overlay during the falloff after being corrected for the difference in gauge depths. On occasion, abrupt temperature changes can be seen to correspond to trends in the pressure data. Although the source of the temperature changes may remain unexplainable, the apparent correlation of the temperature anomaly to the pressure anomaly can be sufficient reason to question the validity of the test and eliminate it from further analysis.

- The data that is obtained from pressure transient testing should not collect dust, but be compared to petition or permit parameters. Test derived transmissibilities and static pressures can confirm compliance with no migration and non-endangerment (AOR) conditions.

APPENDIX D-VII

MS IZ 1 Conversion Plan and Schematic

Conversion Plan for Minerva South In-Zone Well No. 001

Stream 34 Well No. 001
SN: 224951, API: 17019219190000
Cameron Parish, LA
(Map ID 1)

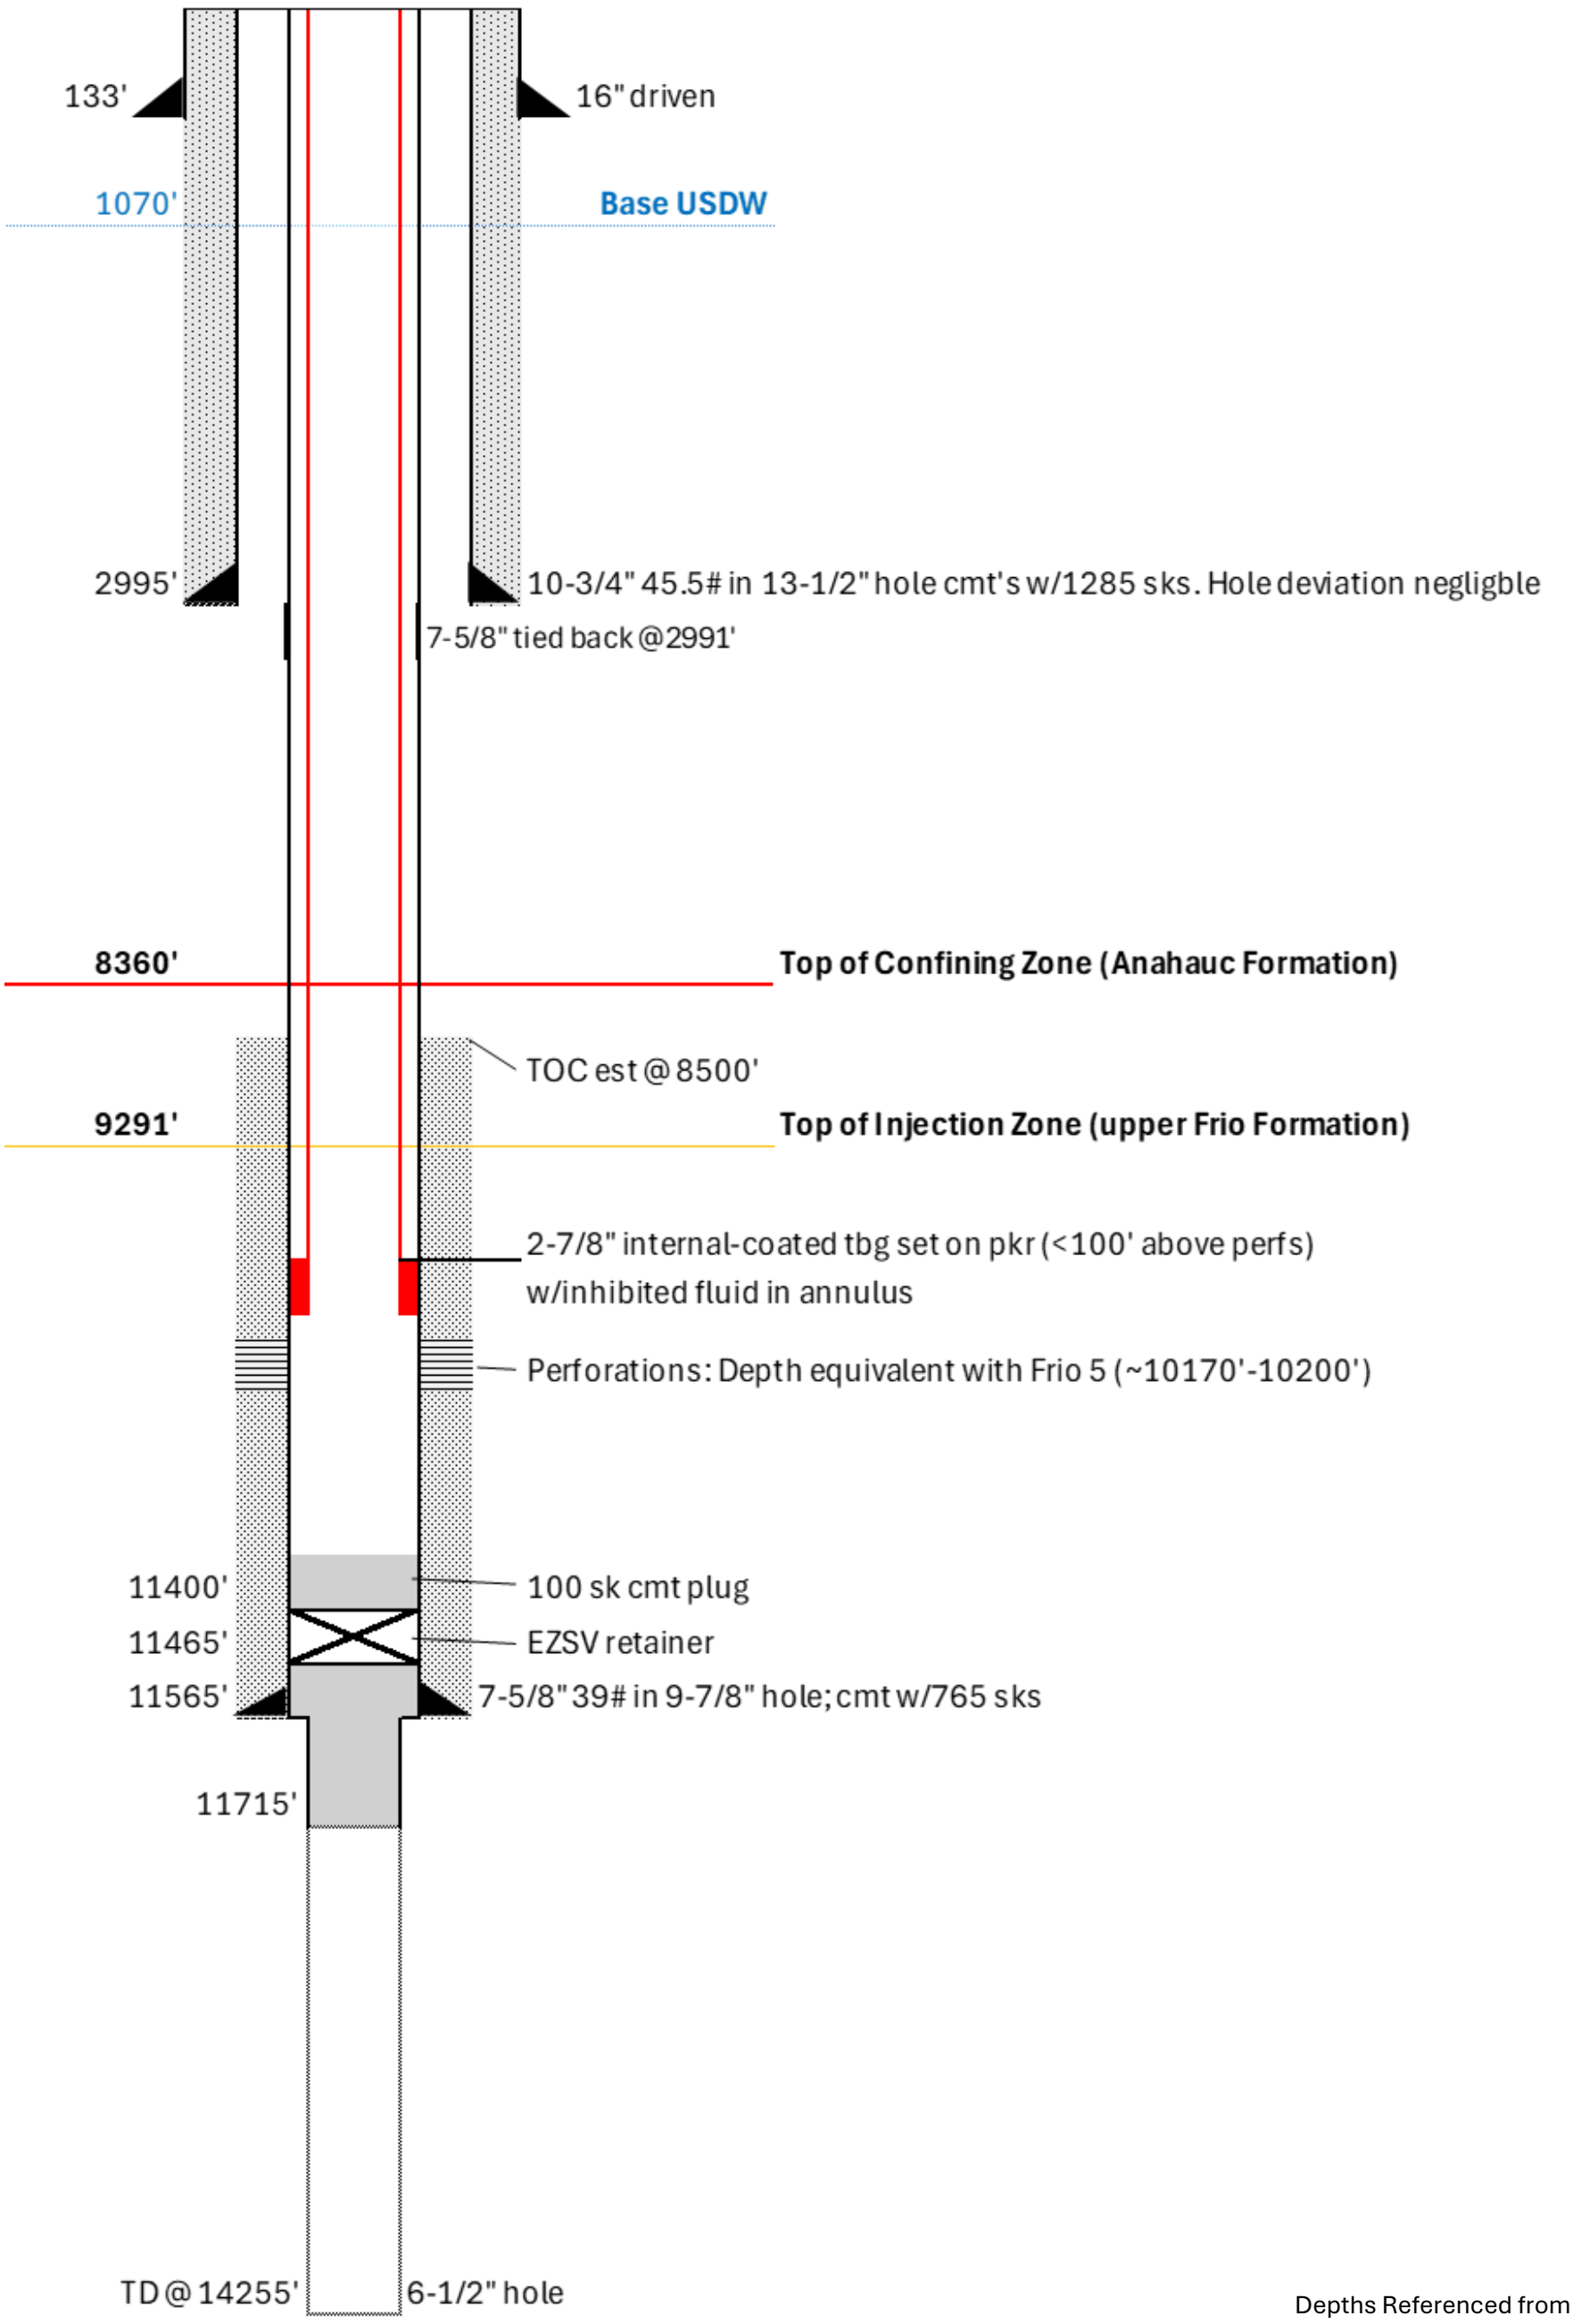
RE-ENTER WELL, EVALUATE EXTERNAL CMT ON 7-5/8" & EQUIP AS A MONITOR WELL

RE-ENTER AND TIE-BACK PRODUCTION CSG

1. Locate plugged wellhead and build location
2. After locating csg stub, tie sfc csg back to sfc and install flange and wellhead and BOP equipment.
3. MIRU, pick up workstring and bit to drill out sfc plugs, tagging up on 7-5/8" cut csg @ 2991. (Note one report in file states csg was cut @ 2945.)
4. POOH and pick up shoe to wash over and dress off +/- 15' cut csg.
5. POOH and pick up csg patch and 7-5/8" csg to tie back production csg to surface.
6. Install wellhead & BOP equipment.

CLEAN OUT WELLBORE

7. RIH w/bit to drill out cmt inside cut csg.
8. Continue drilling out cmt inside 7-5/8" csg and RIH to 11,400'.
9. Cir well clean w/KCL & POOH. Pressure test csg and record same.



EVALUATE CEMENT BOND

10. Run CBL, temp log and BHP survey.
11. Results from Cmt bond:
    a. If sufficient bonded cmt exists along the base of the Confining Zone (Anahuac Formation), POOH and continue with "in-zone" monitor well plans
    b. If insufficient cmt is bonded along the base of the Confining Zone (Anahuac Formation)
        i. Perforate csg 100' below and above the Confining Zone (Anahuac Formation)/ Injection Zone (Upper Frio Formation) (CZ/IZ) boundary
        ii. Set cmt retainer above lower perforations & attempt a wrap-around sqz extending 100' below and 100' above top of CZ/IZ boundary
        iii. Pull out of retainer and let cmt set up
        iv. Drill out cmt down to the retainer and run CBL to confirm TOC bond with CBL.
        v. If CBL is satisfactory, drill out cmt retainer and cmt. Otherwise, re-sqz and affirm sufficient bond is in place.

COMPLETE AS "IN-ZONE" MONITORING WELL

12. RIH w/ 2-7/8" internally-coated tbg string and 7-5/8" pkr no higher than 100' above initial Injection Zone (Upper Frio Formation) monitoring perforations (TBD).
13. Cir inhibited fluid on tbg/csg annulus.
14. Set pkr and perform and record csg integrity test.
15. Perforate Upper Frio Formation thru-tbg within the initial Injection Zone at a depth TBD. Perforations will be aligned with interval perforated in proposed injection wells.
16. Run temp log, BHP survey and fluid movement survey (to test external mechanical integrity).
17. Install wellhead and tree equipped with isolation & swab valves and pressure recording devices
    a. Monitor wellhead and annulus pressure
    b. Periodically sample air space in wellhead for presence of CO_2 and/or hydrocarbons
    c. Periodically, run suite of logs/surveys to monitor fluid movement behind pipe

Indirect Monitoring Technology Specifications

Distributed Acoustic Sensing (DAS)

Fiber optic acoustic monitoring for subsea wells

The **SureVIEW™ seismic distributed acoustic sensing (sDAS) interrogator** offers all of the benefits of fiber optic acoustic monitoring—from flow monitoring and optimization, sand detection and stimulation optimization, to seismic and microseismic monitoring—combined in a single interrogator unit.

Unlike other DAS interrogators, SureVIEW sDAS utilizes Baker Hughes SureVIEW **CoreBright™ optical fiber**, a proprietary fiber specifically designed for durable oil and gas deployments. This allows operators to monitor high value assets through the life of the well, from well-centric to reservoir focused scales.

The combination of SureVIEW sDAS with **CoreBright™ enhanced backscatter fiber (EBF)** permits the acquisition of data in subsea wells located long distances from the data acquisition unit. Testing shows that a vertical seismic profile (VSP) can be acquired from the shore, or host facility up to 50 miles (80 km) away.

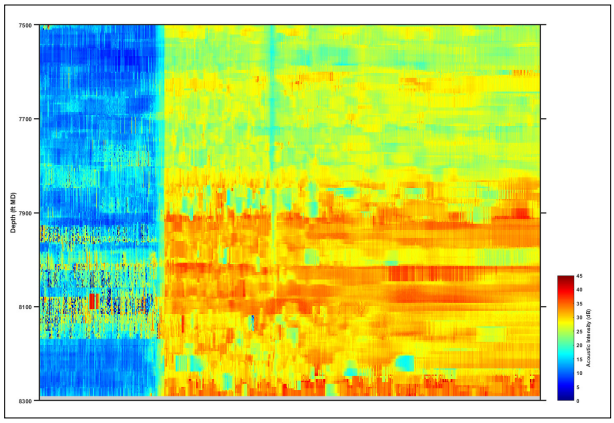
The SureVIEW sDAS interrogator can output various formats, suitable for various applications, and has the ability to break down the raw data, as well as compute attributes on-the-fly (frequency-band energy, individual spectra). It can also record data either in continuous or trigger mode, and is equipped with an independent global positioning system (GPS)–thus permitting clock synchronization and clock drift control.

SureVIEW sDAS delivers high fidelity data readily available to processing and answer solution teams. The system may also be remotely operated through a connection to the Baker Hughes cloud services, and is compliant with HDF5 data format.

From seismic processing, reservoir characterization, data visualization and advanced modelling and interpretation, we deliver answers, not just data.

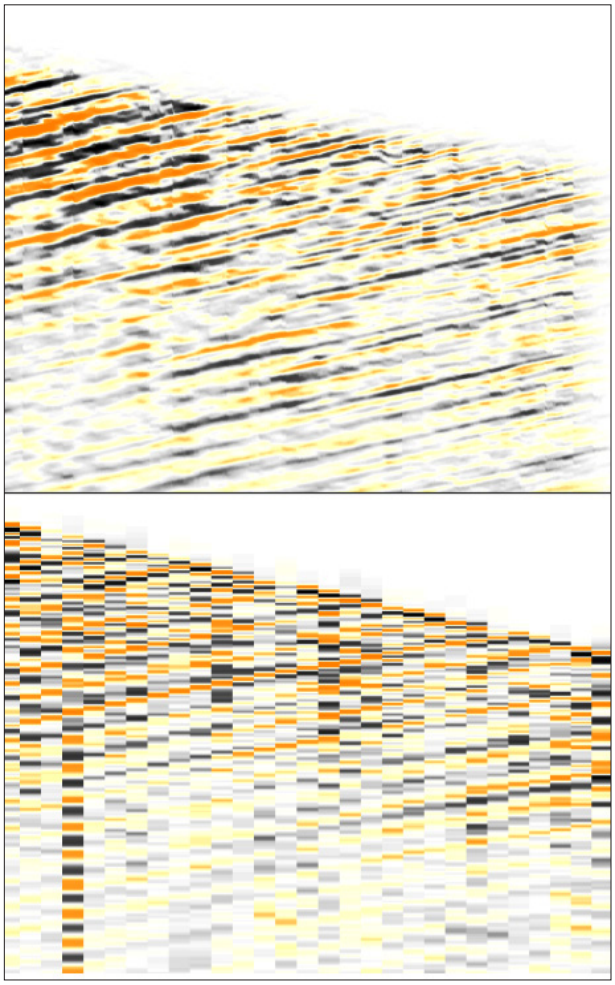
Contact a Baker Hughes representative today to learn how we can help you take energy forward.

Applications



- Subsea and land wells
- Permanent reservoir monitoring
  - Flow monitoring
  - Sand detection
  - Leak detection
  - Stimulation optimization
  - Microseismic monitoring
  - Vertical seismic profiling (VSP)

Benefits



- Delivers an integrated solution from subsurface equipment to remote visualization and analytics that saves time and cost
- Simplifies handling and management of data reducing IT integration time
- Offers a better understanding of the wellbore/reservoir enabling sustained and/or incremental production of your asset
- Enables understanding of the entire completion when coupled with Baker Hughes SureCONNECT™ downhole intelligent wet-connect system
- Provides a long-term well and reservoir monitoring solution while reducing operating costs by minimizing/eliminating unnecessary interventions

Technical Specifications

Technology Supported	SureVIEW DAS VSP
Type	Rackmount
Number of Channels	8
Rack Unit Dimensions	6U
Certifications	CE, TUV
Supply Voltage	110-240 Volts AC, 50 or 60Hz
Typical Power Consumption	Up to 400W
Operating Temperature Range	0°C to +40°C / 32°F to +104°F
Optical Connectors	F3000/APC
Interface Connections	Ethernet, GPS, USB (Geophones) DC Trigger Pulse (GPS Synced)
File Formats	PRODML/HDF5/SEG-Y
Data Storage	960GB (Internal) 8TB (NAS)
Maximum Distance Range	Up to 12 miles (20 km) with CoreBright fiber Up to 50 miles (80 km) with CoreBright EBF
Fiber Type	Single Mode
Spatial Resolution	1.5 meter
Minimum Sampling Interval	0.33 meter
Gauge Length	Selectable 3, 7, 15, 31 meters
Maximum Pulse Rate	10 kHz
Dynamic Range	0.24 nε (over full bandwidth) 1.5pε (narrowband) Up to 1 με

This Distributed Acoustic Sensing (DAS) Frequency Band Energy (FBE) shows acoustic energy acquired in a multi-zone injection well. This information was used to estimate zonal flow allocation.

This comparison shows the upgoing wavefield of a vertical seismic profile (VSP) acquired above the well with a wireline tool (bottom) versus 43 miles (69 km) away from the wellhead (top) with sDAS, and CoreBright™ as lead-in fiber, a 3dB attenuation and a subsea amplifier, and CoreBright™ EBF inside the well.

Pulse Neutron Capture Log

DCN: W17R008.A2

RESERVOIR PERFORMANCE MONITOR (RPM)

Advancing Reservoir Performance
Formation evaluation and reservoir monitoring

TIER 1

COMPREHENSIVE RESERVOIR EVALUATION AND MANAGEMENT

The Reservoir Performance Monitor (RPM™) platform is an advanced, slimhole, multifunction, pulsed neutron reservoir monitoring instrument. Its instrumentation combines multiple nuclear measurements in one system with industry-leading accuracy and precision. Carbon/oxygen (C/O) and pulsed neutron capture (PNC) measurements acquired with the RPM tool provide water saturation and three-phase holdup determination, while oxygen activation measurements allow detection of water flow and channels.

RPM services address a broad scope of reservoir evaluation and management applications, including reservoir saturation and produced fluids monitoring, formation evaluation, production profiling, workover and well abandonment evaluation, borehole diagnostics, location of bypassed oil, gas detection and quantification, and identification of water production.

The RPM instrument employs three high-resolution gammaray detectors arrayed above an efficient and reliable neutron generator. State-of-the-art detector electronics measure both the arrival time and energy of detected gamma rays. The generator is pulsed at distinct frequencies, and the data acquisition system operates in various timing modes to obtain the different logging measurements. The system hardware is combinable with other production logging instruments; and it is constructed in short, modular sections to facilitate shipping and handling.

ACCURACY IS PARAMOUNT

The accuracy of the RPM service has been ensured by extensive physical characterization in Baker Hughes' Houston Technology Center. The tool's measurements have also been enhanced by 3-D and Monte Carlo modeling to provide accurate response in a wide range of borehole, casing, formation, and fluid conditions; and Baker Hughes' unique Dynamic Response Generator™ feature delivers accuracy and confidence in any borehole geometry.

Unique downhole conditions can be modeled to ensure that analysis of the reservoir is the most accurate available. And extensive pre-job planning tools are available for design of a data acquisition program that optimizes the final answers delivered by the service.

EFFICIENCY IS DESIGNED IN

Flexibility and operating efficiency make the RPM tool a complete multimode, multisensor, solution-based system. All operating modes are selectable by surface commands.

The RPM instrument can be run in combination with conventional production logging sensors to provide a complete picture of a well's production and reserves in a single trip. It can also be combined with Baker Hughes' unique Multi-Capacitance Flow Meter (MCFM™) instrument in the POLARIS™ system for evaluation of highly deviated wells.

WHY THE RPM TOOL WORKS SO WELL

The RPM instrument uses high-energy neutrons to measure both the inelastic and capture gamma rays.

The inelastic gamma rays, produced by fast neutron collisions during the accelerator pulse, are used for carbon/oxygen measurement to determine the formation water saturation in formations with fresh or unknown connate water salinity.

The capture gamma rays, generated by the absorption of slow or "thermal" neutrons after the pulse, are used to measure formation water saturation in formations with saline connate water. The sensitivity of the capture process to salinity produces a log response similar to a conductivity measurement, where the measured thermal neutron absorption cross section (∑) is used to determine water saturation.

Baker Hughes

RESERVOIR PERFORMANCE MONITOR (RPM)

TIER 1

APPLICATIONS AND SOLUTIONS

FORMATION EVALUATION

- Cased hole water and gas saturation measurements
  - Through casing (with through-tubing deployment capability)
  - When openhole logs are unavailable or uneconomical
- Quantification of total hydrocarbons in medium- to high-salinity conditions
- Quantification of liquid hydrocarbons in low- and mixed-salinity conditions
- Identification and quantification of gas, independent of salinity
- Evaluation of porosity
- Identification of mineralogy

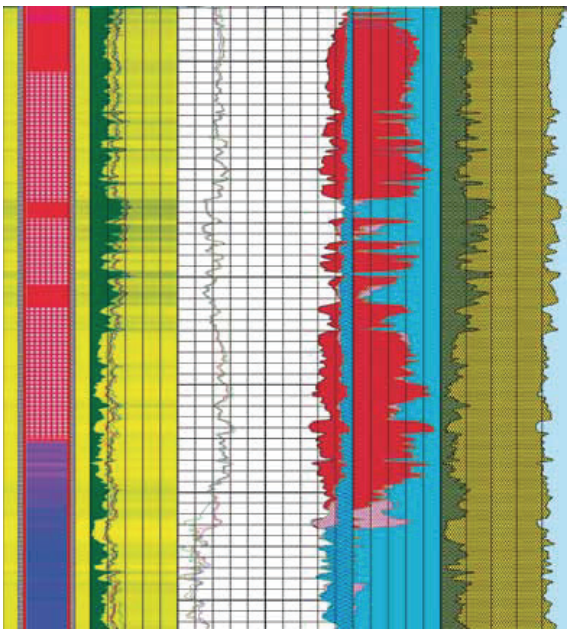
RESERVOIR MONITORING AND MANAGEMENT

- Monitoring fluid contacts
  - Time-lapse fluid monitoring
  - Gas/oil/water contact levels
  - Production and reservoir depletion
  - Identification of bypassed hydrocarbons
- Reservoir management base logs

BOREHOLE DIAGNOSTICS

- Identification of water channeling and casing leaks
- Production/injection profiling in multiple-string completions
- Multiphase borehole fluid holdup determination

WORKOVER APPLICATIONS



- Location of bypassed hydrocarbons, independent of water salinities
- Evaluation of stimulation operations
- Log-inject-log surveys for determining irreducible hydrocarbons
- Production/injection profiling

The RPM instrument employs three high-resolution gamma-ray detectors arrayed above an efficient and reliable neutron generator.

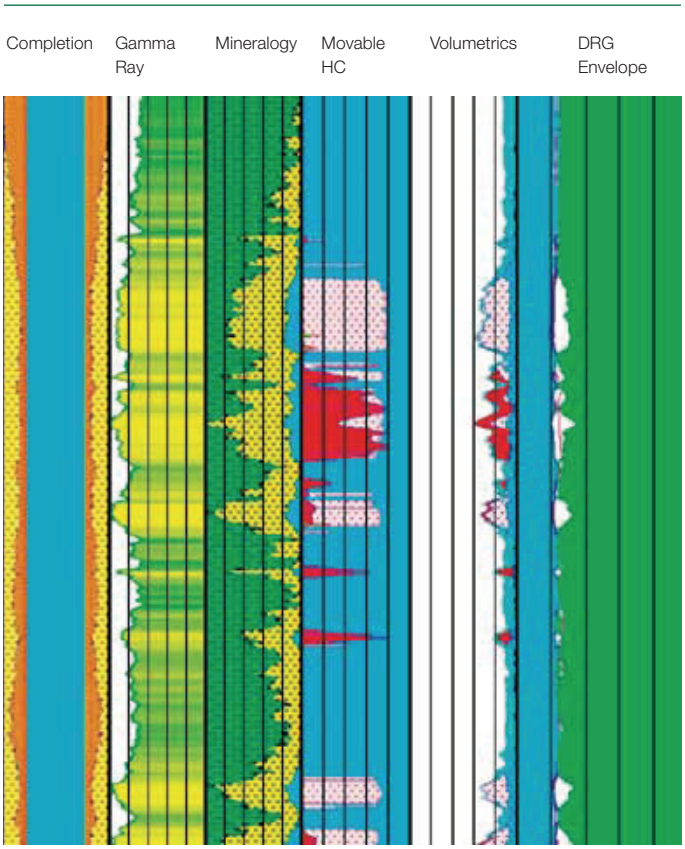
PULSED NEUTRON CAPTURE

In the Pulsed Neutron Capture (PNC) logging mode, the detectors record the arrival time of the gamma rays, from which the formation ∑ is determined. Time spectra from short-spaced and long-spaced detectors can be processed individually to provide traditional ∑ information. The multiple spectra are processed simultaneously to correct for borehole and diffusion effects, producing a real-time corrected formation ∑ measurement. Multiple additional measurements are provided to measure formation porosity, shale volume, and borehole fluid changes, as well as to identify formation gas.

Advanced interpretation of PNC data is available through Baker Hughes' GEOScience centers using the SEARCH™ analysis program. The identification of gas zones and the measurement of formation gas saturation is performed using the PNC mode. In this application, Baker Hughes combines special instrumentation, response characterization, and an interpretation algorithm to produce a state-of-the-art gas measurement.

Apparent measurements from near and far detectors are combined to produce a real-time corrected formation ∑.

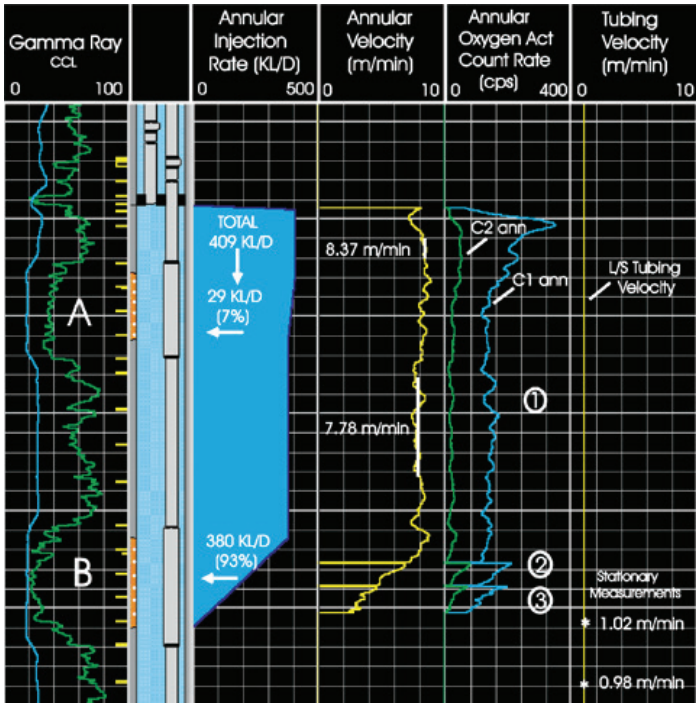
Baker Hughes



RESERVOIR PERFORMANCE MONITOR (RPM)

TIER 1

CARBON/OXYGEN LOGGING



When formation waters are fresh, brackish, or of mixed or unknown salinity, the RPM-C/O acquisition mode is used to detect hydrocarbons. In this mode, direct measurements of the oxygen and carbon content of the reservoir are made, allowing differentiation of hydrocarbon zones from water-bearing zones.

Since chlorine has virtually no inelastic reaction cross section, the C/O measurement can be used to determine formation water saturation independent of salinity.

Interpretation of basic C/O data for monitoring hydrocarbon depletion of a sandstone reservoir.

FOUR MODES FOR OPERATING VERSATILITY

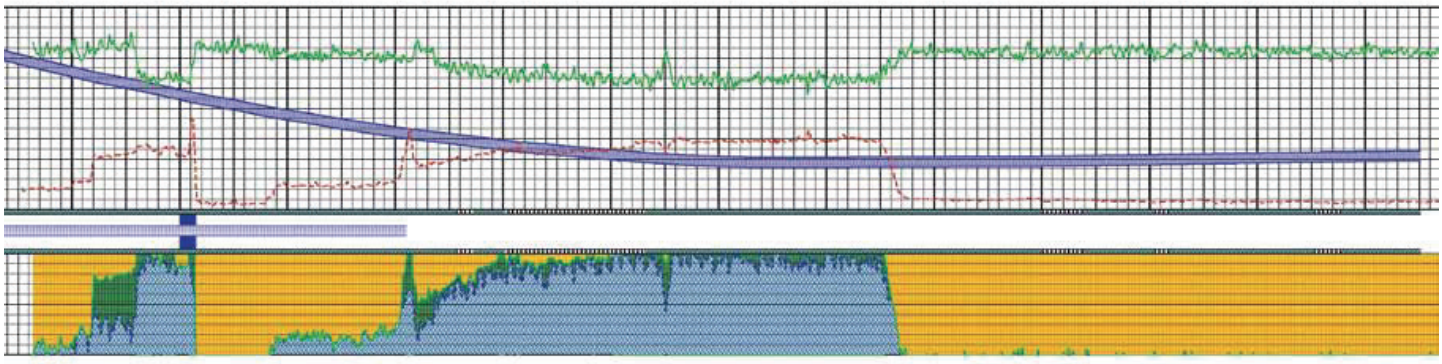
AFL volumetric analysis in a dual-string injection well determined that 7% of the injected fluids were entering zone A and 93% were going into zone B.

WATER FLOW LOGGING

The RPM Annular Flow Log (AFL™) and Hydrolog™ measurements use the principle of oxygen activation to measure water flow. In this application, oxygen is made artificially and temporarily radioactive through the neutronexchange reaction, allowing it to be used as a short-lived tracer. Detection of the movement of the activated oxygen can determine water velocity. These measurements provide a powerful diagnostic tool to identify movement inside the casing, outside the casing, or in the tubing-casing annulus. The measurement techniques allow detection of water movement from 2 to 500 feet per minute in simple and complex completions.

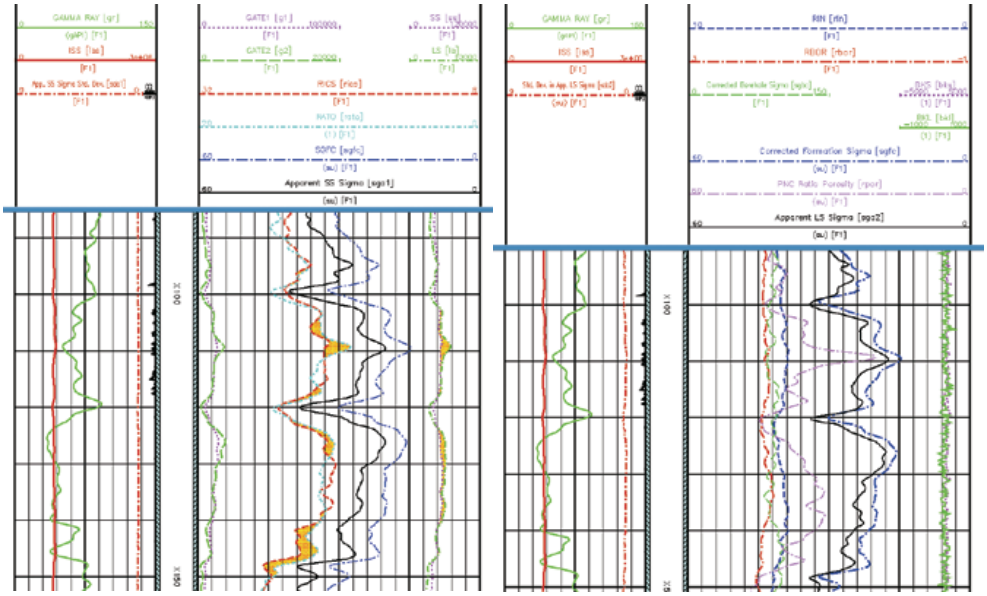
Baker Hughes

RESERVOIR PERFORMANCE MONITOR (RPM)



TIER 1

LOG YOUR MOST HOSTILE WELLS



The RPM-C instrument can provide accurate data in wells in which other pulsed neutron tools cannot even survive. It has industry-best standard environmental specifications of 350°F (177°C) and 20,000 psi (138 MPa). Specially modified hardware enables reliable service at temperatures to 500°F (260°C) and pressures to 30,000 psi (207 MPa).

HOLDUP IMAGING

The RPM Pulsed Neutron Holdup Imager (PNHI™) logging mode was designed for measurement of holdups of gas, oil, and water in horizontal boreholes. The PNHI measurement produces a continuous image of the borehole contents, independent of flow regime and unaffected by gravity segregation of the produced fluids.

The PNHI log can determine gas, oil, and water holdups in horizontal boreholes.

Although RPM-PNC data acquisition and processing provide analysis results and statistics that are superior to conventional PDK-100 measurements, the RPM-PNC log display and PDK-100 presentation are similar. In time-lapse studies, an emulation of the PDK-100 curve can be provided with RPM-PNC processing for easy comparison of their measurements.

BUILD ON THE DATA YOU ALREADY HAVE

RPM data can be matched with previous-generation PDK-100™ measurements for easy comparison in mature fields. The RPM service provides real-time emulation of PDK-100 measurements for comparison with historical logs. For remedial work and timelapse monitoring, RPM data can be overlaid with existing log measurements in real time, allowing rapid workover planning.

An advanced feature of the RPM service allows real-time computation of “intrinsic” ∑. Innovative data analysis techniques provide a ∑ measurement that is corrected for borehole and diffusion effects, without prior knowledge of borehole salinity.

OUR EXPERIENCE AT YOUR SERVICE

Expert support at the wellsite and from the Baker Hughes GEOScience Center provide the foundation for superior reservoir surveillance solutions.

Since inception, Tier 1 has provided cased-hole logging services. When required, we work with technology leaders that provide specific logging solutions. The RPM from Baker Hughes is an example of how Tier 1 will provide the best in service quality while deploying logging equipment supported by the experts of the technology.

Baker Hughes

APPENDIX D-IX

VSP Feasibility Study

U Frio VSP Feasibility Study

Scope of Work

Baker Hughes was contracted to assist Gulf Coast Sequestration in evaluating which seismic technique would be optimal for indirect monitoring of a CO_2 plume in the upper Frio Formation within the Minerva south project. All information in this document is based on the reservoir information provided by Gulf Coast Sequestration.

The study's first objective was to determine if appreciable changes in seismic signals would occur from fluid replacement (CO_2 replacing water via injection). When appreciable changes do not occur, false positives (and/or false negatives) obscure seismic methods from interpretating plume geometry. With the information available today, this study suggests that there is high confidence that sufficient changes in the seismic signature will be present within the upper Frio Formation to track the CO_2 plume via VSP and also via other seismic methods. Since appreciable changes were found, the study took on a second objective and investigated what would be the optimal seismic method. The acquisition geometry was optimized for a VSP. The optimal VSP geometry was constrained by a combination of cost, confidence in the 4D response, and size of monitored area. The findings of this optimal VSP acquisition were then placed into the context of other seismic methods and a cost analysis was made between 3D VSP and other seismic methods (2D surface seismic simultaneous with 2D walkaway VSP, 3D surface seismic (high definition), and other new surface monitoring technologies.

Seismic Rock Physics

Rock physics allows us to predict attributes, such as velocity or density from physical properties such as porosity, fluid saturation, and mineralogy (sand, clay, etc.). Our aim within this study was to construct a Rock Physics model to predict how density and velocity will change as fluid changes from water to supercritical CO_2. Figure 1 demonstrates how dry mineral components and porosity were prepared for use in the Xu-White method. This option is used to derive Vp, Vs and Rho using the Xu and White (1995) clay-sand mixture model and the Kuster and Toksoz (1974) differential effective medium (DEM) equations (Keys and Xu, 2002).

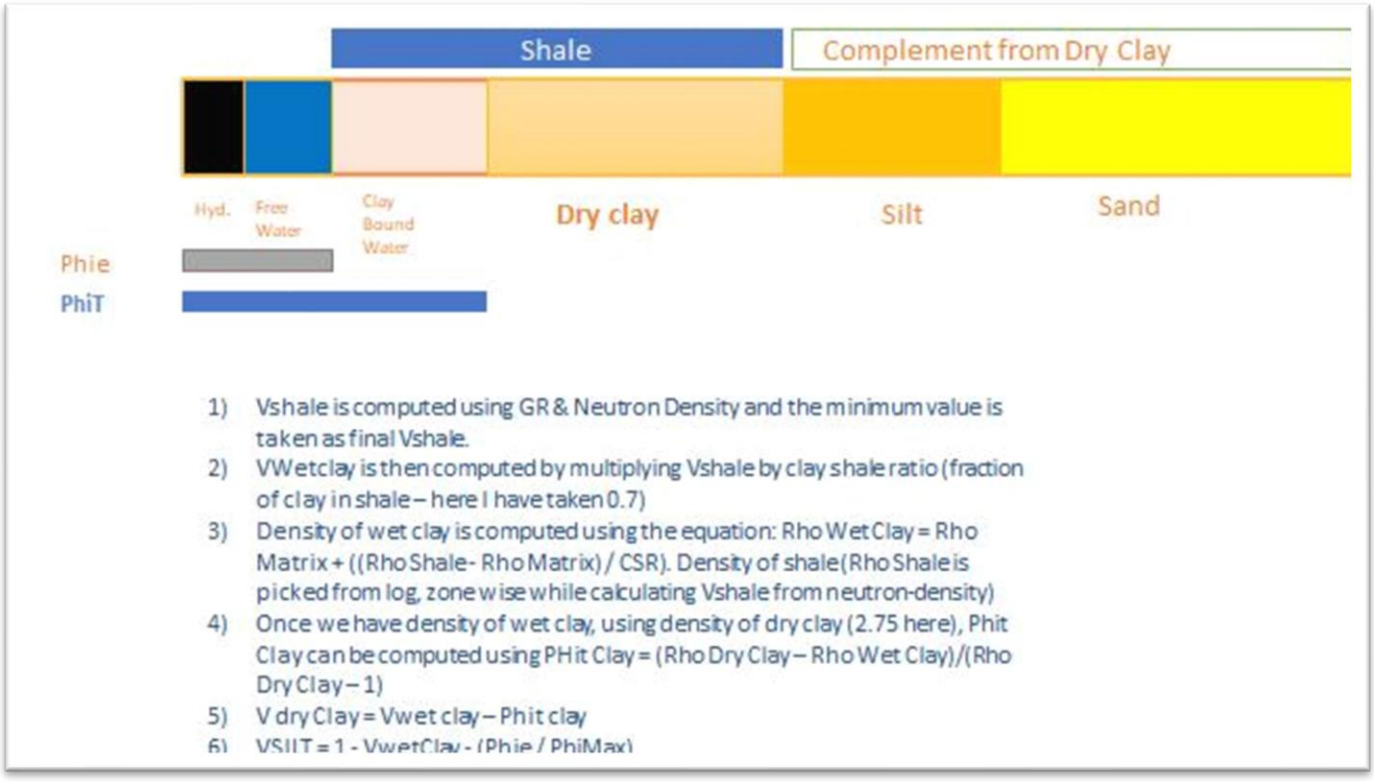

Figure. 1 Rock Physics Model

The Xu-White method allowed us to predict an S-wave velocity, a P-wave, and density using a table of dry minerals properties. As input to this method, total porosity, saturation, and dry clays are necessary. The predicted curves are compared to the measured (p-sonic and density) and table or log analysis are modified until a good match between measured and modeled responses are achieved.

Using the provided log analysis, S-wave and Poisson's ratio were estimated as in-situ. Fluid replacement modelling was carried out using the results as input and 100% water as output. This was done for all the wells; the results below are shown for one well. For the fluid replacement model, CO_2 using 80% was modeled to evaluate the changes in acoustic impedance.

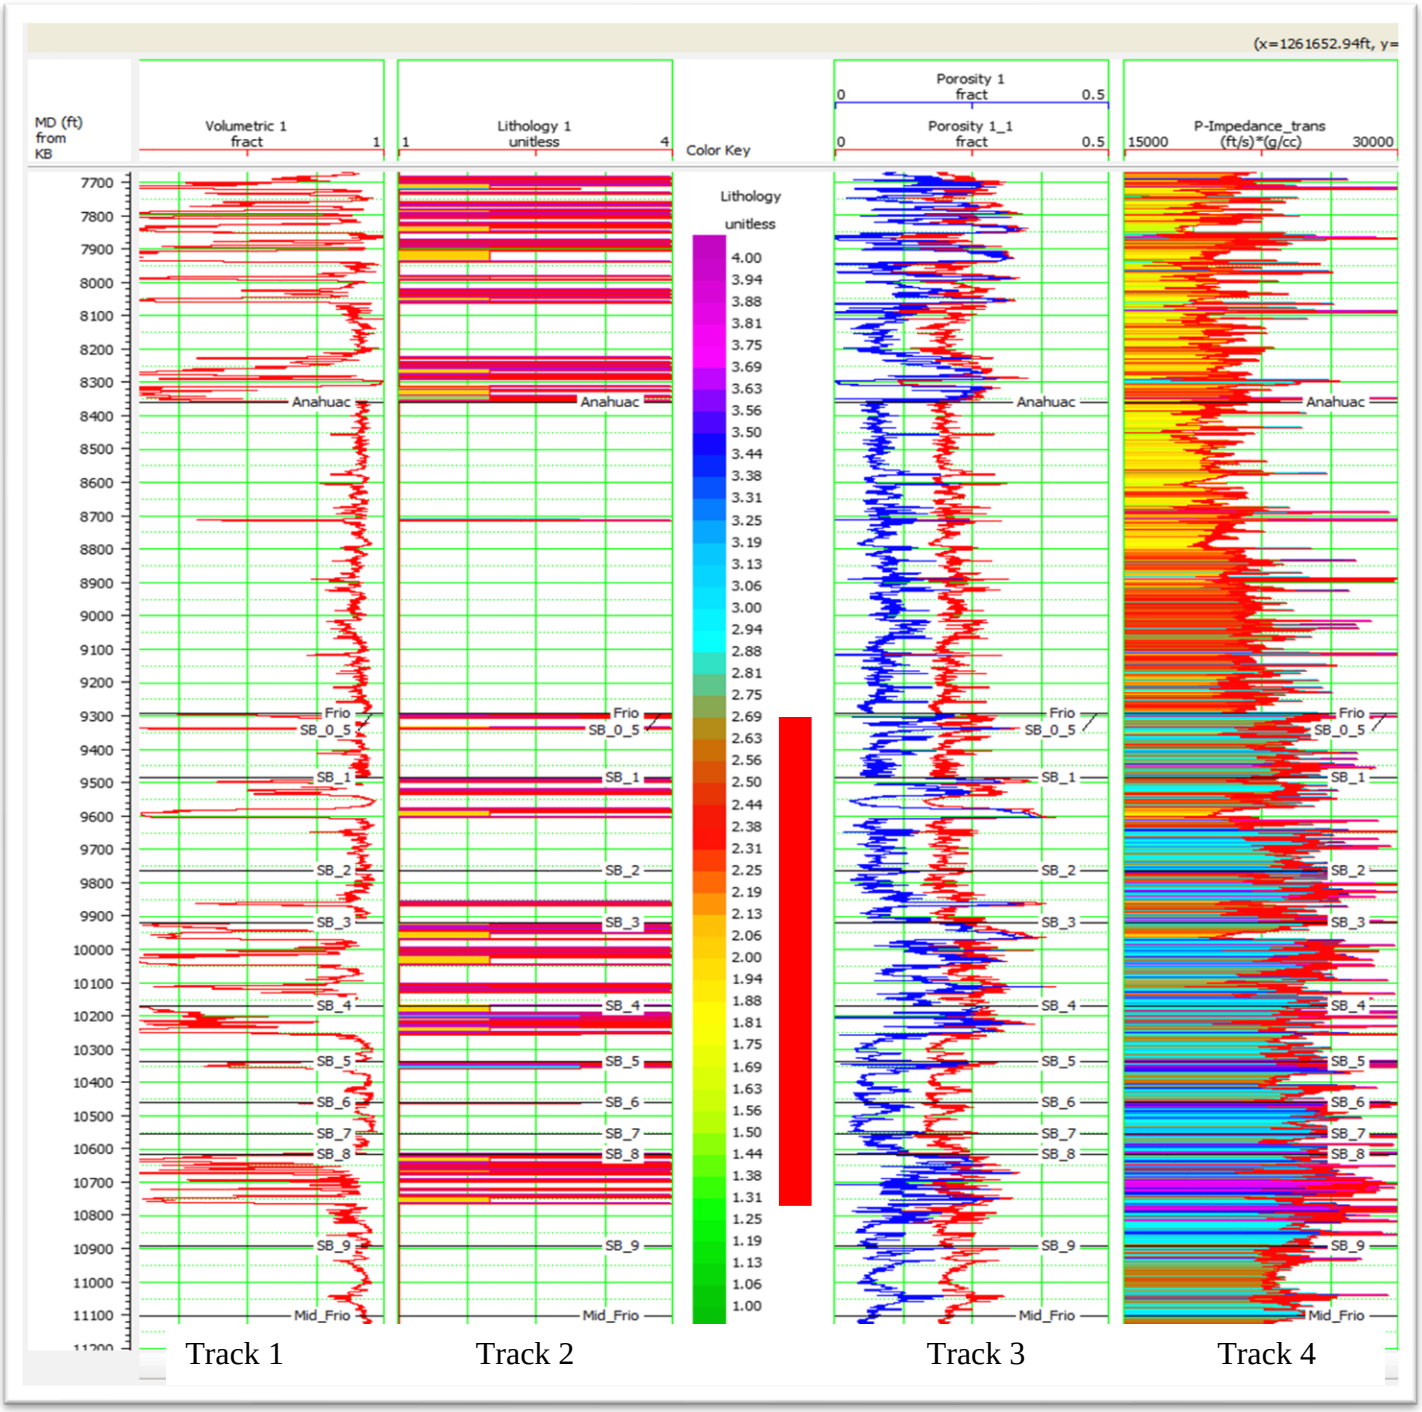

Figure 2. Input curves, supplied by the client and used in rock physics.

The fluid replacement results (Figures 3) confirm that the presence of CO_2 (80%) will change the acoustic impedance on average 15% - track 4- (5% is the noise level detectability in seismic).

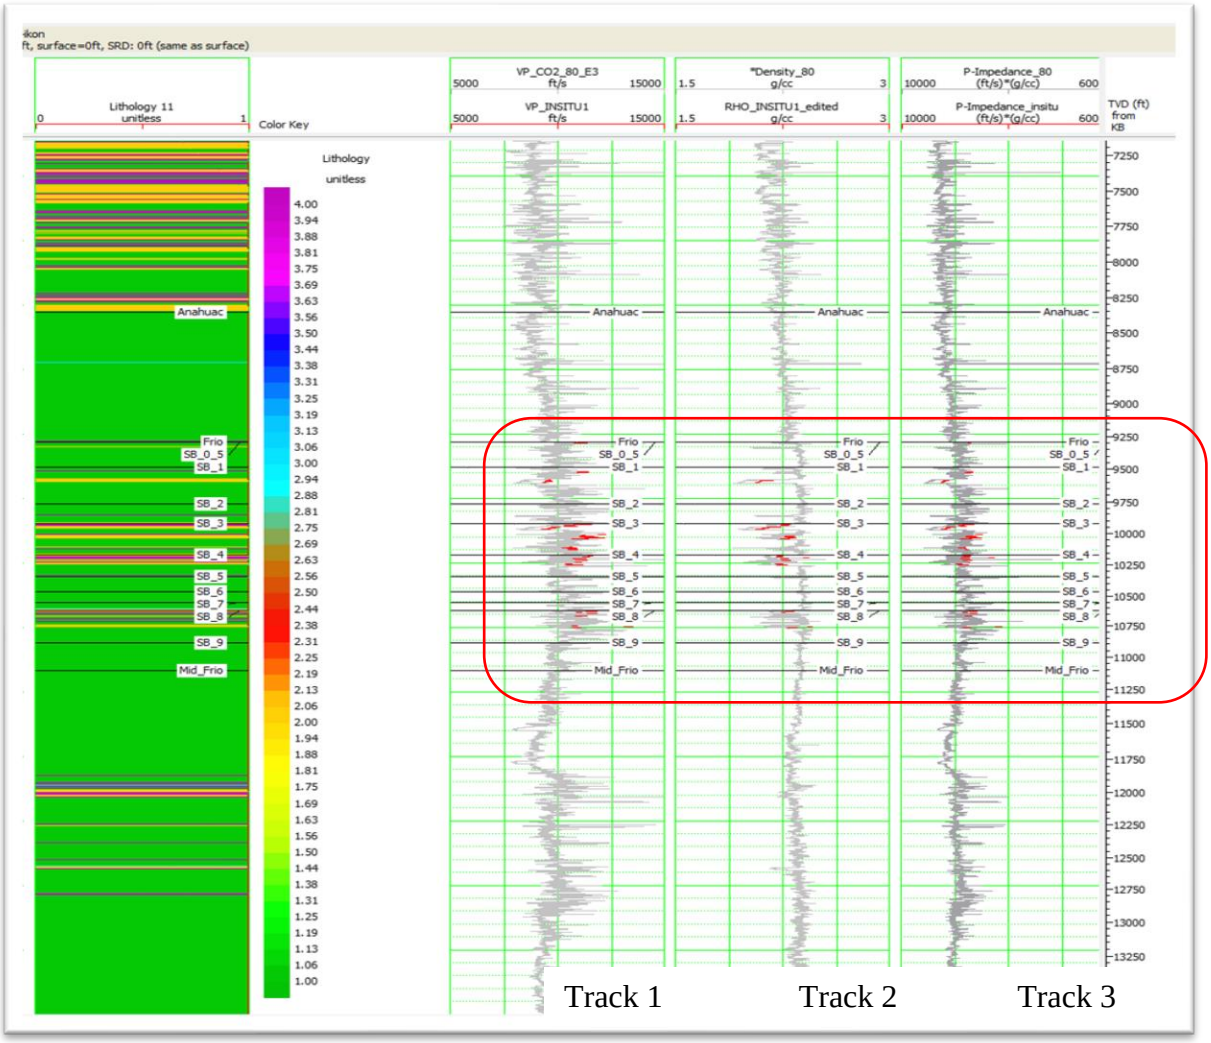

Figure 3: Shows the P-wave (Track 1), density (Track 2), and impedance (Track 3) before and after the fluid substitution. Note where the changes are happening in red shading.

Amplitude versus offset synthetic models were then generated to illustrate these changes (Figure 4), without loss and with loss of energy., Both results indicated that seismic changes are observed with the presence C. Track 1 is the volume of quartz and Track 2 is the lithology facies: red is Quartz. Track 3 is total porosity (red) and effective porosity (blue). Track 4 shows impedance. The red bar indicates the possible injection zones.

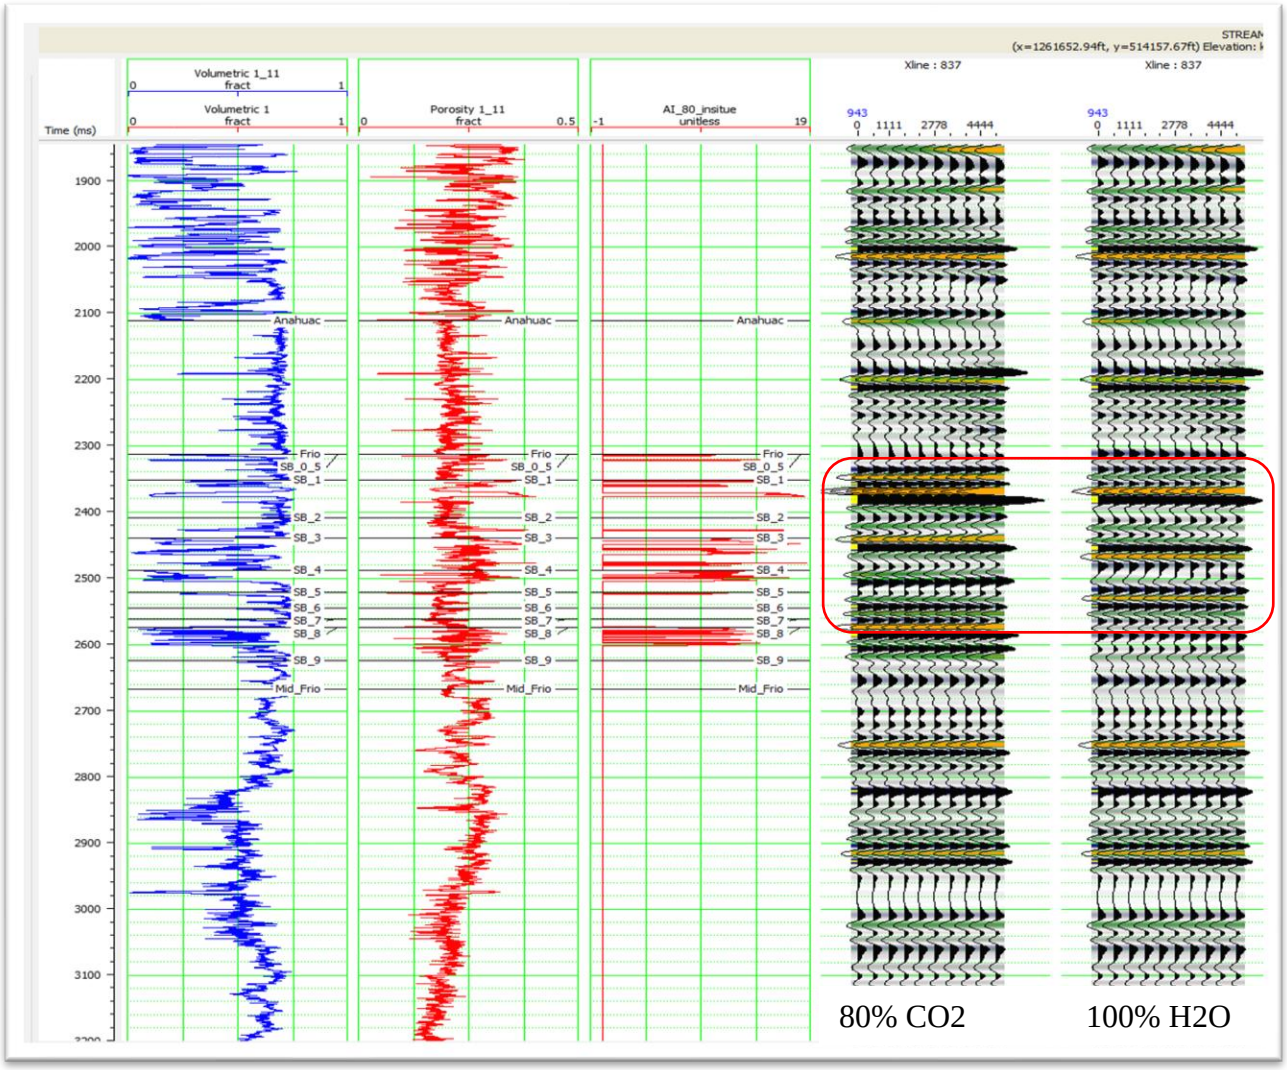

Figure 4. Synthetic AVO Model - results from the fluid substitution 80% CO_2 and 100% H_2O. Note the changes in amplitudes caused by the CO_2.

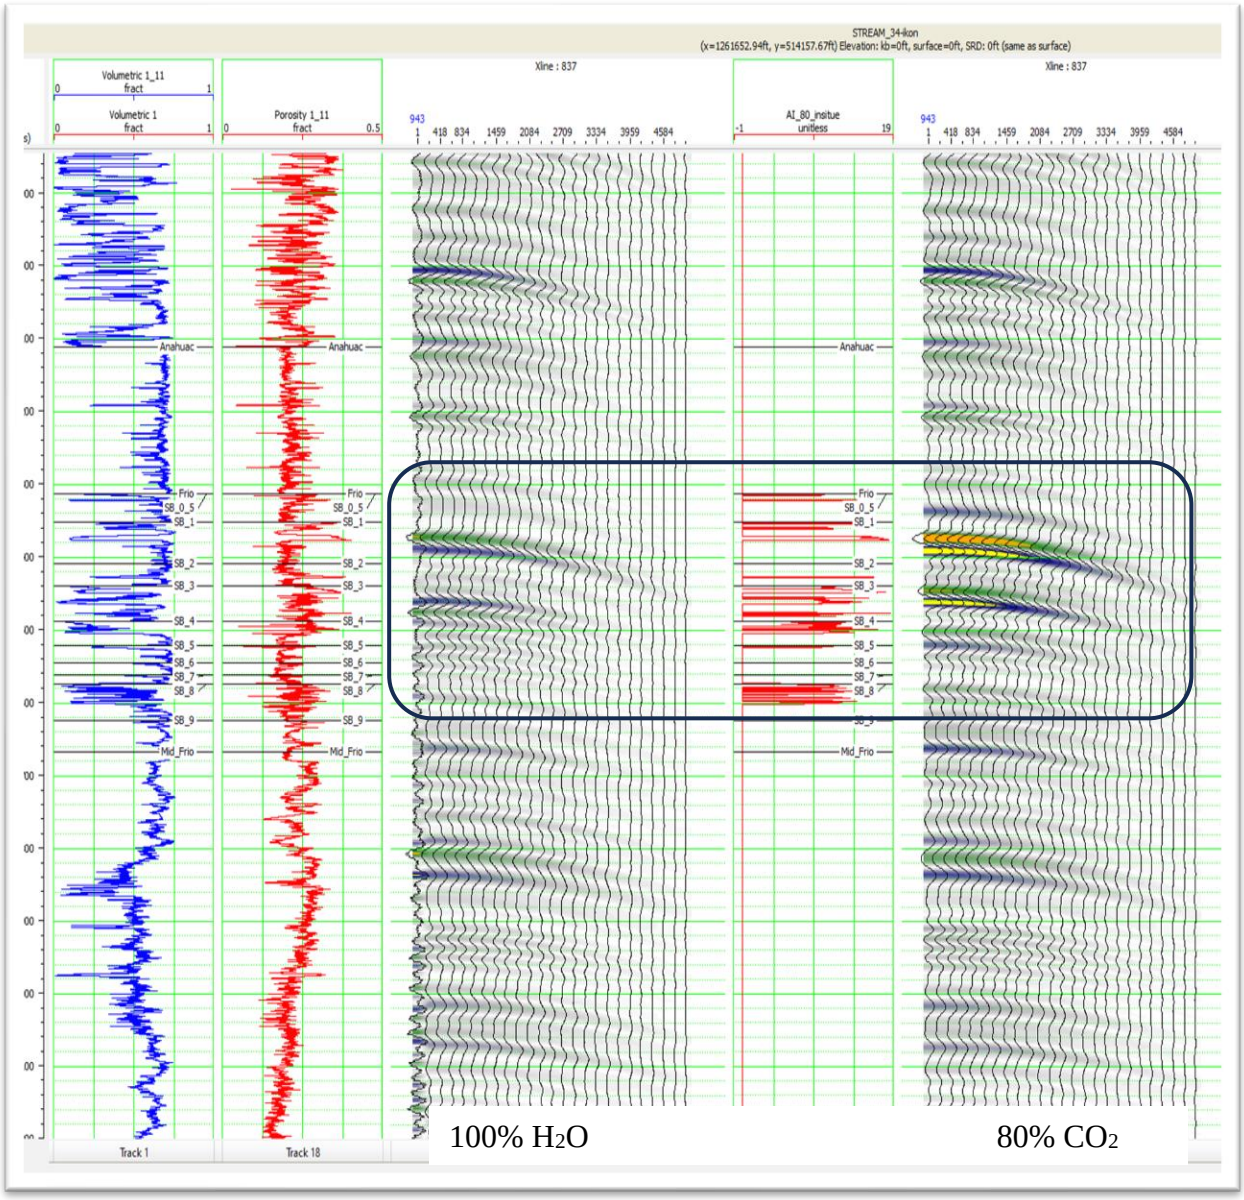

Figure 5. Shows the bright spot cause by CO_2, confirming that the seismic methods will work.

ILLUMINATION 3D VSP FOR MONITORING

Model Building

A 3D P-wave velocity model was build using horizons supplied by the client and the Streamer-34 well (Figure 6).

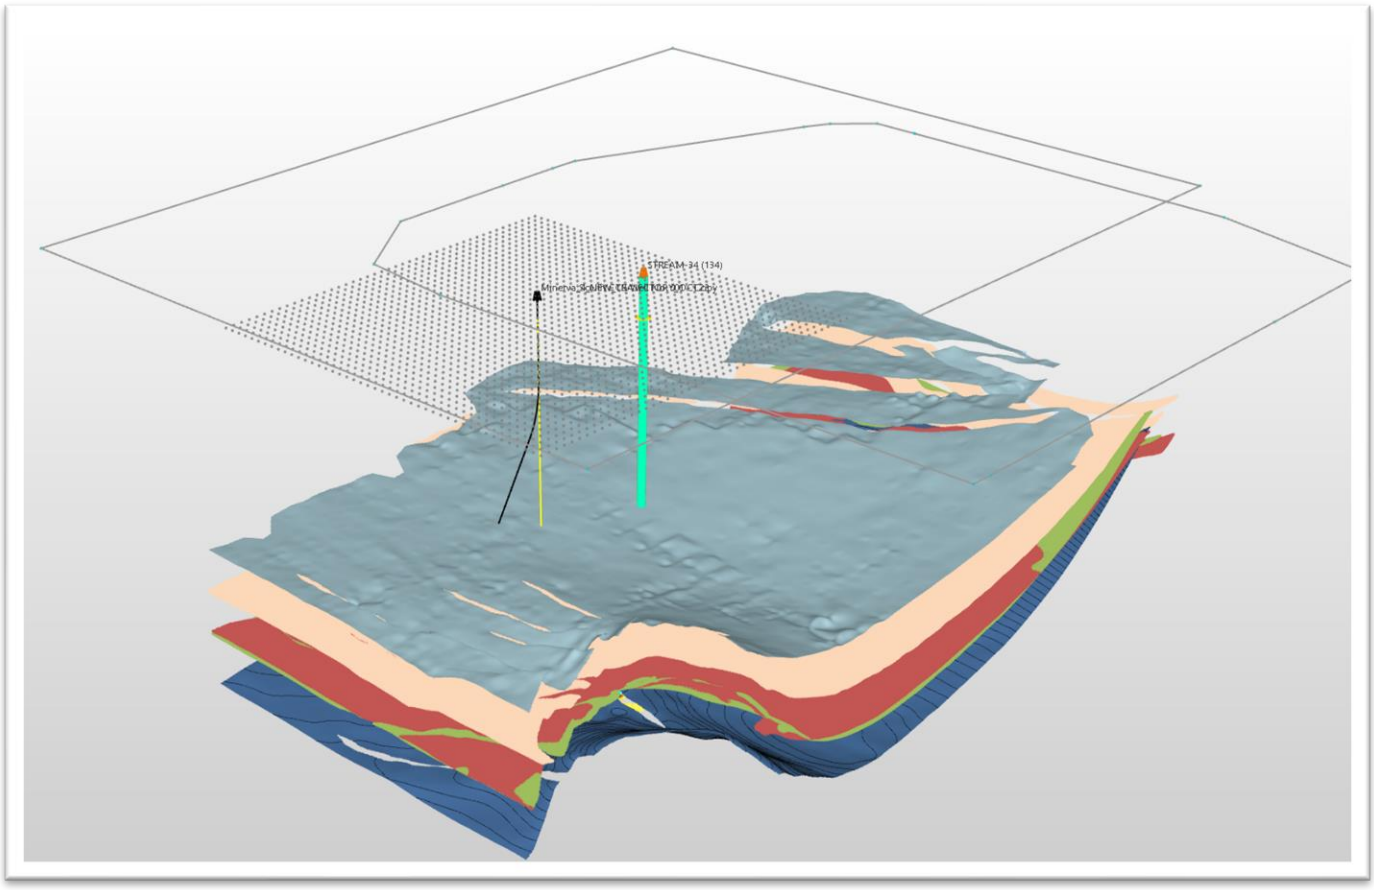

Figure 6- Main horizons for the upper Frio Formation used to build the velocity field. Calibrated well is in green (MS CCS 1).

3D VSP Illumination

Using the proposed well location MS CCS-1 (vertical) and a monitored DAS interval from 500-9,500 ft, an illumination exercise using ray tracing to Mid Frio was ran. The illumination fold is demonstrated for a given acquisition geometry as a Blue-Green-Yellow–Orange-Red surface (Figure 7). This illumination fold counts how many seismic rays impinge upon the upper Frio Formation layer from the set of sources and the set of receivers in the DAS fiber. The higher the fold, the more measurements we have in a particular area and the greater confidence there is in the measurement.

The extent of the upper Frio surface illumination is smaller than the footprint of the receivers. This is due to the critical ray path constraining the distance between the injector well and the plume. Now that the aerial extent of the image is known, we can understand whether this covers the AoR. Given what we understand about the evolution of the plume, this illumination exercise suggests that the usability of the 3D VSP is limited to approximately 10-years for this acquisition geometry. The maximum illumination of the surface using 3D VSP does not allow to extend beyond the 10-years for monitoring purposes of the plume extension. Therefore, after 10-years, the monitoring program will need to be replaced with 2D lines and Walk-Away VSPs. Appreciable changes in source footprint will not substantially improve the overall utility of VSP beyond this 10-year timeframe. Afterwards, conventional 2D lines combined with Walk-Away VSPs will be used to monitor further the changes.

Two extra locations for monitoring were also modeled, but the areas selected cannot be used due to the current surface conditions. As a results, additional seismic techniques have been proposed.

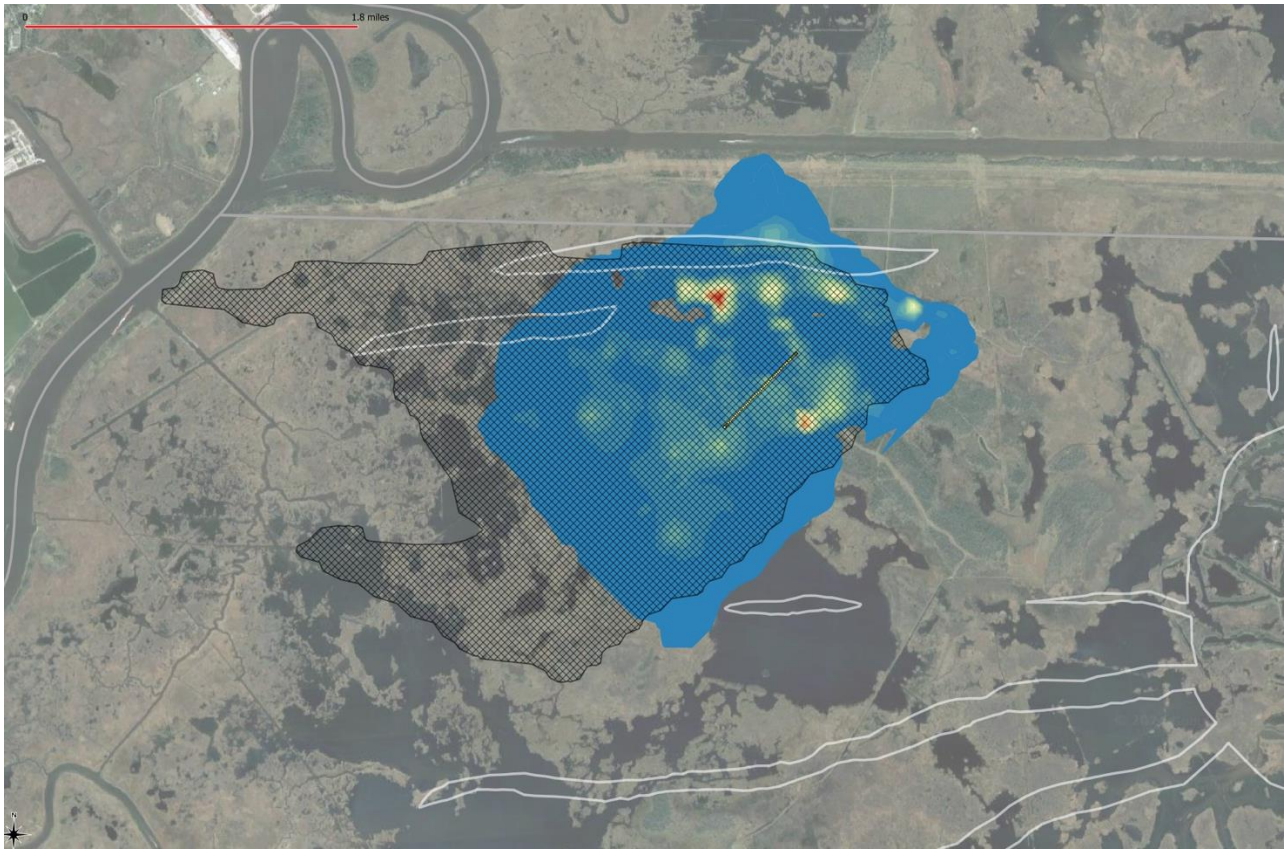

Figure 7. 3D illumination fold is shown in the contour colors– Note: after 10 years another seismic method needs to be used. Dash plume correspond to 75 years.

2D Seismic Illumination

A 2D line was extracted from the existent 3D volume and the center part was replaced with the CO_2 responses (Figure 7.)

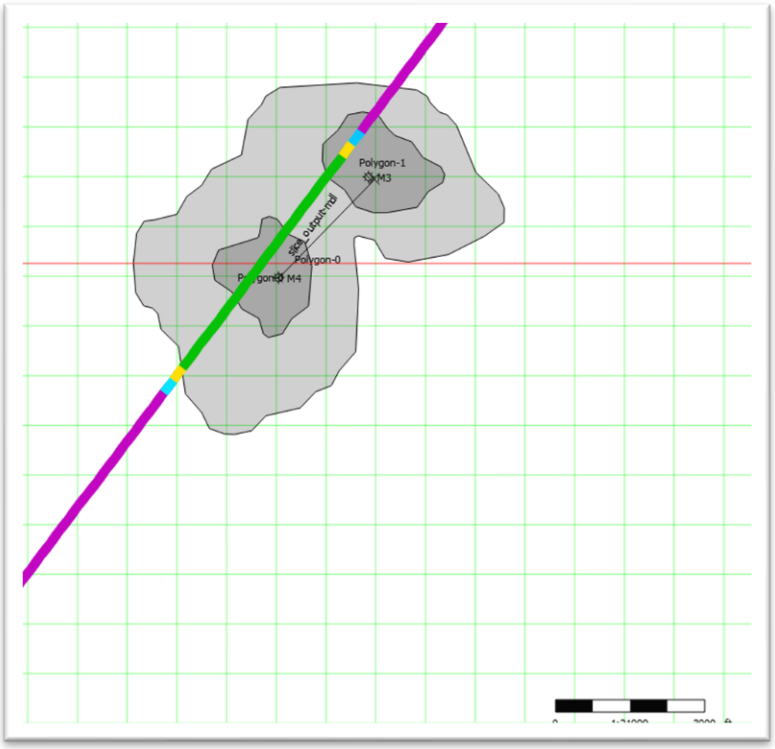

Figure 8. 2D Line extracted from the 3D volume.

Using an acoustic model (P-wave and density, Figure 8.); a normal Incident model was generated with two different frequencies. Note that a 4D effect is observed (Figure 9),.

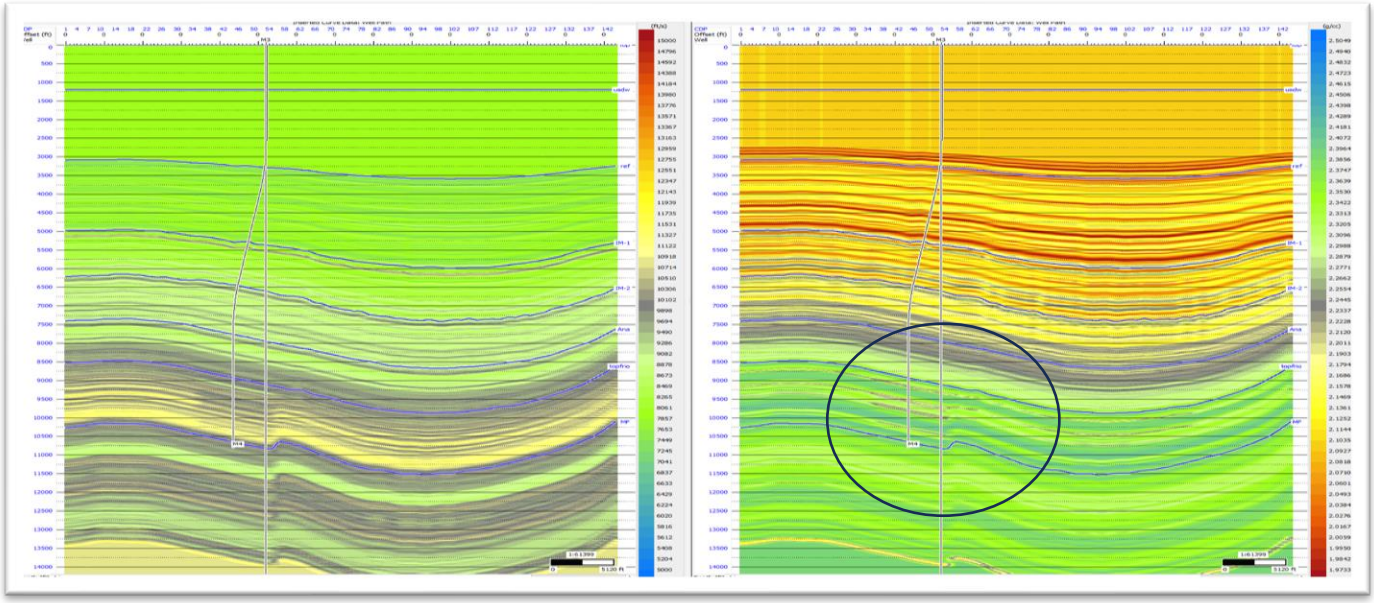

Figure 9. P-wave and Density model used for the Acoustic Model. Injection zone highlighted within the circle.

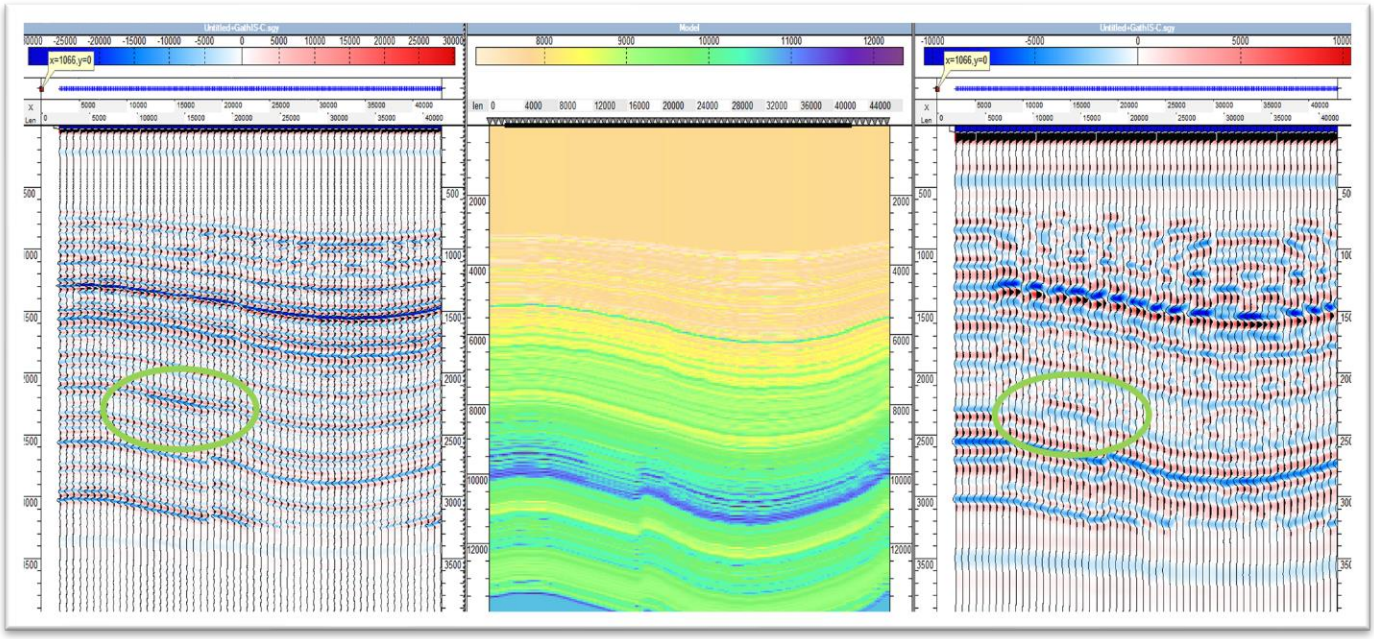

Figure 10. Normal Incident synthetic generated to simulate 2D Seismic line acquisition. The 4D effect is highlighted in the green circle.

Conclusions

1. With the expected plume migration and the reservoir properties provided from the upper Frio Formation, seismic methods can be used to track the CO_2 plume.

2. The injection well can be used to monitor the plume using a 3D VSP with an approximate coverage of no more than 10-years (based on the forecast plume model).

3. 2D conventional seismic methods will work in the area as an alternative method to monitor the plume after year 10.

4. Baseline acquisition of at least the 2 seismic methods listed below is required before the injection starts:

    1. 3D VSP Study (Figurer 10)
    2. 2D surface seismic simultaneous with 2D walkaway VSP (Figure 11)

The costs illustrated below on each acquisition method are preliminary and do not include the cost to lay the receivers, permits, etc. The cost is a guide to illustrate the differences between each method.

3D VSP Survey

Pro: 3D Image, higher vertical resolution.

Cons: Useful for only 10-years of monitoring (from the forecast plume area).

Frequency: Base Line, 5 years, 10 years or at any time that changes do not agree with the prediction triggered/measured by the Walk-Away VSPs.

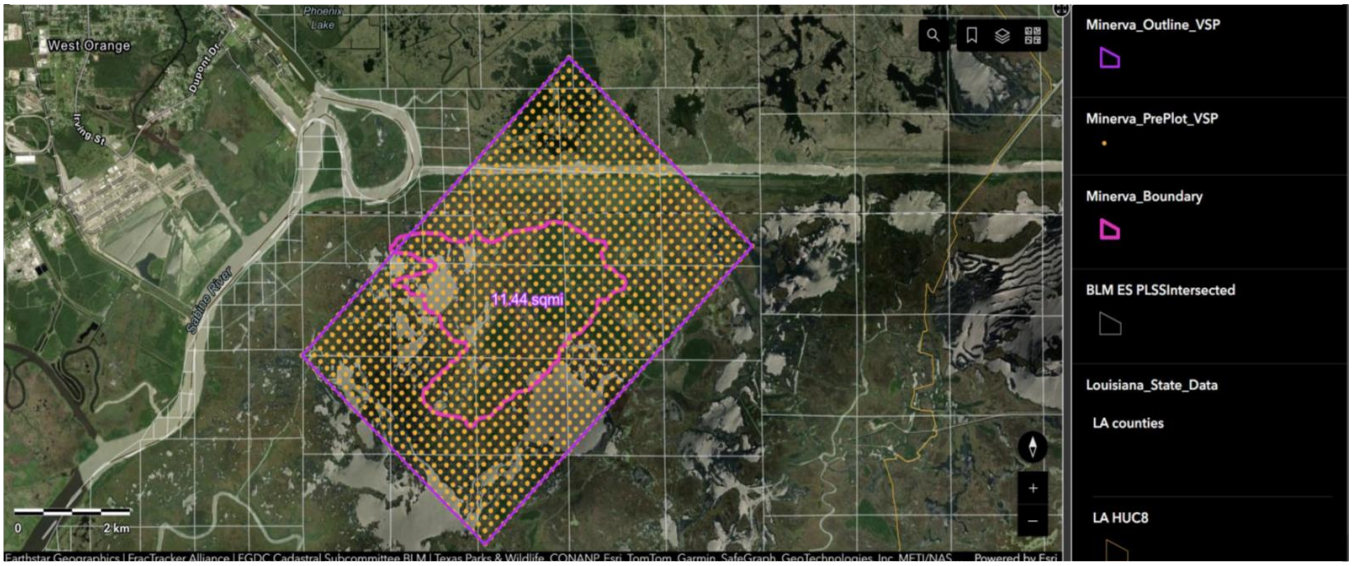

Figure 11. The is 3D VSP shooting in yellow. Pink is the estimated plume size for 10 years. And 11.44 square kilometer area, with sources planned on a 500' x 500' grid with recommended 5.5 lbs pentolite charge loaded 100' deep. With this source only grid, 1,350 source points would be recorded as VSP. The datasets may be used for 3D monitoring in the future. As such, the design and acquisition of the survey must account for repeatability.

2D Surface Seismic Simultaneous with 2D Walkaway VSP

Pros: 2D Image, higher vertical resolution, monitor lifetime of the project; pseudo 3D image can be generated.

Cons: 2D image along the lines - could be mitigated by generating pseudo 3D's

Frequency: Baseline (year 0), every 12 months the WalkAway VSP will be shot and will determine if more detailed monitor information is needed after the model has been calibrated. The more detailed image will come from the 3D VSP. After

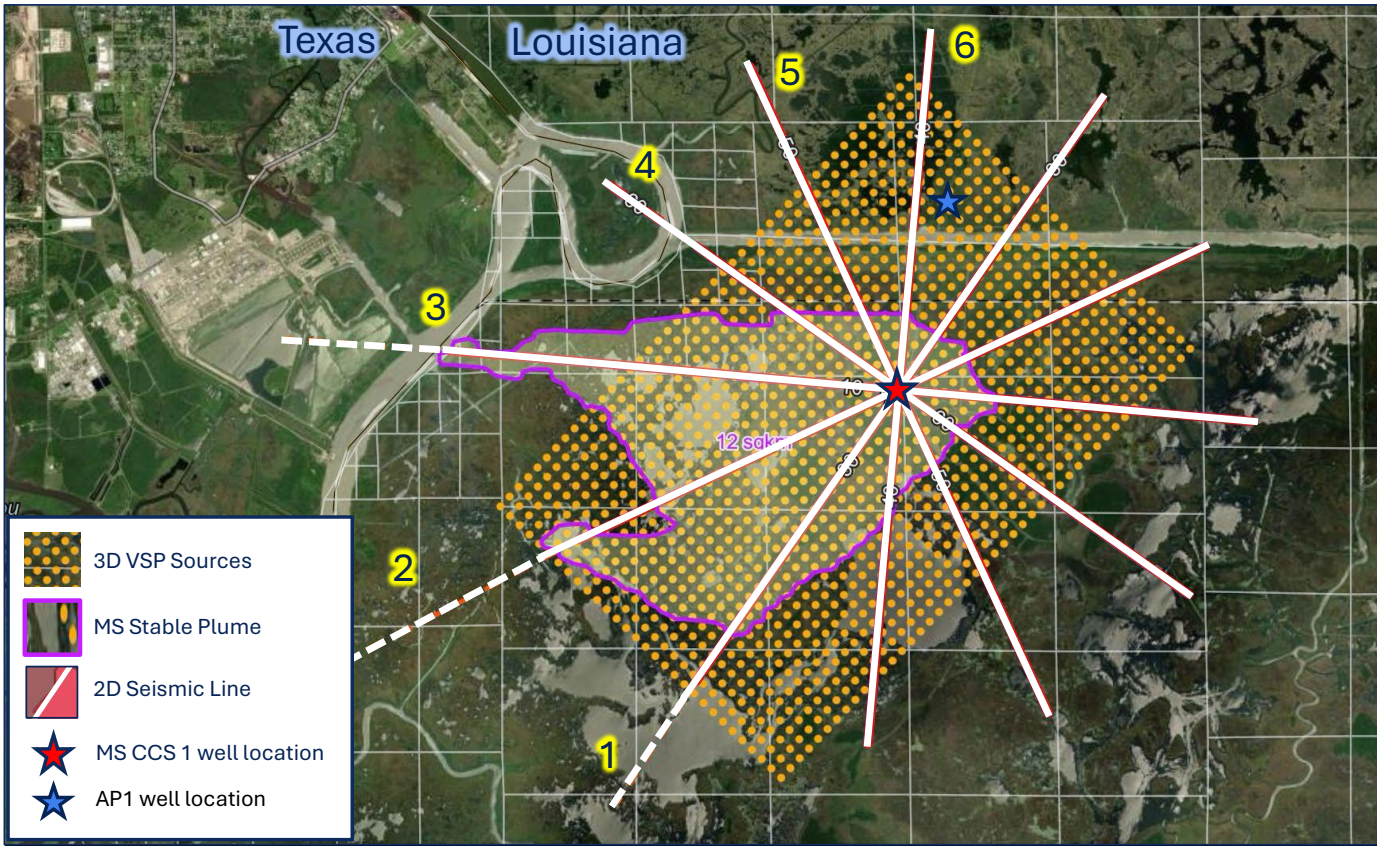

Figure 11: 2D lines program to monitor the plume migration to be acquired simultaneous with VSPs. The 2D star pattern cannot use the same sources as the 3D VSP, as those are sparse and not in line with the receivers, therefore, the 2D lines need its own sources. The star pattern 2D sources and receivers are ONLY along the 2D lines. It is suggested a 27.5' receiver interval and a 55' source interval, which results in ~2,979 source points. The idea here is that the source points will be recorded both by surface sensors that we deploy, and by the downhole receivers that Baker Hughes deploys. The star pattern is achieved by placing 6 walkaway lines, centered on the well, each rotated 30 degrees. VSP data would be acquired using fiber optic cable cemented behind casing in a vertical well. The source point type and the source point interval were not specified, the acquisition company recommends scoping in advance of any testing.

Ikon SCIENCE

Executive Summary

Gulf Coast Sequestration, LLC (GCS) will build and operate the country's premiere geologic sequestration asset to capture carbon dioxide (CO_2) and safely contain it underground at their Minerva project in Louisiana.

Ikon Science provided Quantitative Interpretation services to allow GCS to have a better understanding of the elastic changes in the subsurface study that can be expected during sequestration, specifically focused on properly monitor the CO_2 plume. In addition, Ikon has provided baseline 3D characterization of the Minerva project area to assist with delineation of the sandstone units.

Ikon Science's technical workflow included petrophysics review, rock physics and seismic modeling, which correspond, respectively, to the 1st, 2nd and 3rd phases of the project.

This report covered the following phases related to the baseline 3D characterization:
Phase 1: Seismic data review and qc, in which three seismic surveys were evaluated.
Phase 6: Seismic data conditioning. seismic to well-ties
Phase 7: Seismic inversion
Phase 8: Reservoir characterization

In Phase1, legacy 3D seismic datasets were analyzed for quality and consistency. Two surveys in the north were reviewed, the Big Island 3D and Alligator Cove Merge 3D. In the south the Black Bayou 3D was reviewed. All surveys contained post-stack processed data, while the Alligator Cove Merge survey also had pre-stack seismic data available.

In Phase 6, seismic data conditioning (SDC) was carried out to the partial angle stacks of Alligator survey. Comparison of the seismic traces before and after SDC showed clear improvement in terms of SNR and lateral continuity of seismic traces. For Black the Bayou survey, data conditioning was applied to the post-stack dataset. Seismic to well ties were carried out for the wells that were part of the Rock Physics Study, as well as for two wells that are in the southern portion of the Black Bayou survey: Gray Matilda-2, Texaco_E_and_P_Etal-3.

Post-stack seismic inversion was subsequently carried out on the Black Bayou survey, which provided the greatest coverage of the sequestration area. Ji-FI (Joint Impedance and Facies Inversion) provided an estimate of the most the most likely facies (sand and shale) from the seismic data, along with the corresponding acoustic impedance. The acoustic impedance volume has a reasonable match with the acoustic logs (AI) for the well Stream-34. A subset of the sandstones at the well were matched by inverted seismic facies. The correlation of well and seismic facies was limited by both seismic resolution and the small difference in the acoustic impedance of sandstones and shales at some depths. There was a fair match with the Texaco_E_and_P_Etal-3 well to the south of the sequestration area.

High amplitude reflections in the post-stack data correlate with some extensive sand bodies from the inversion results extending to the south from the sequestration area. These do not correlate with well control in the south (well Gray Matilda-2) and are considered unlikely to be present in the subsurface. Future characterization with additional wells and/or pre-stack data would provide more constraint on these features.

In the Phase 7, the Ji-Fi inversion acoustic Impedance (AI) was used to create 3D cubes of total porosity (PHIT) and effective porosity (PHIE). To generate reservoir property volumes, total porosity (PHIT) and effective porosity (PHIE) were estimated by a linear transform calibrated using the well log data. Results showed a reasonable match in the north in the main study area for sand bodies that had been correctly classified by the seismic inversion. These volumes can be used assist in the assessment of sand body extent and porosity in the study area.

Figure 24: Time slice (2550) ms, of Mid Stack (Alligator Cove Merge 3DCrop -Black Bayou grid), and Full Stack of Black Bayou 3D after applied the amplitude match. .. 28
Figure 25 : Base map with well locations..... 29
Figure 26 : The Seismic- Well Tie for Donner-22, using the mid stack conditioned dataset. This well is located at the border of Alligator survey, so the poor seismic-synthetic correlation is not unexpected. The Target interval (Frio), is highlighted in yellow..... 29
Figure 27 : The Seismic Well Tie for Stream-25, using the Mid-Stack conditioned dataset. Overall, a good tie is observed at Frio Interval (highlighted in yellow)..... 30
Figure 28 : Seismic Well Tie for Stream-34, using the Mid-Stack conditioned dataset. This well is located at the southern border of Alligator survey. Overall, this is a fair tie. 30
Figure 29 : Seismic Well Tie for Stream-34, using the conditioned dataset. This well is located at the north border of Black Bayou 3D survey, and the Frio interval and deeper are located on this survey. A good tie can be observed between this well and the Black Bayou dataset..... 31
Figure 30 : Seismic Well Tie for Texaco, using the conditioned dataset. This well is the only one that has the complete measured set of elastic logs. Overall, a good tie has been achieved..... 31
Figure 31 : Seismic Well Tie- Gray-Matilda-2 using the conditioned dataset. Overall, a fair tie between the seismic and the well. 32
Figure 32: Elastic logs and the comparison between the log petrophysical facies and the log elastic facies, for wells Donner-22 and Stream-25. 34
Figure 33: Elastic logs, and the comparison between the log petrophysical facies, and the log elastic facies for Stream-34..... 34
Figure 34: Elastic logs, and the log elastic facies for the wells Gray_Matilda-2, and Texaco_E_AND_P_ETAL-3..... 35
Figure 35: Facies depth trends for sands and Frio Shales (top) and all shales (bottom). 36
Figure 36: Elastic Facies Cross-Plots. Overlap in acoustic impedance between the shales and sands can be seen in the AI-VPVS space (black arrow). 37
Figure 37: Underburden boundary..... 38
Figure 38: East-West depiction of the zones used for the inversion. Note the presence of a salt feature in the canter of the section. 39
Figure 39: Seismic inversion result extracted at Stream-34. Since depth trends are the only input to the inversion, comparison of the results at wells are equivalent to a blind test. We see a reasonable correspondence between both the logs (black curves) and the inversion (red curves) and the facies. 40
Figure 40: Seismic inversion result extracted at the Texaco well. 41
Figure 41: Seismic inversion result at the Gray-Matilda-2 well..... 42
Figure 42: Ji-Fi Inversion most likely facies on a section passing from north to south through wells. Unusually thick sands have been predicted to the south that do not correlate with at the Texaco and Gray Matilda wells. 42
Figure 43: Conditioned Black Bayou Stack. The black circle indicates high amplitudes associated with the thick sandstones highlighted in Figure 42..... 43
Figure 44 : Conditioned Black Bayou Stack trending East-West through a salt feature. 43

Figure 45: The most-likely facies from the JiFi inversion on the section corresponding to Figure 44. The salt intrusion has not been characterized by the facies scheme and is mainly classified as shales. 44
Figure 46: The acoustic impedance corresponding to the facies shown in Figure 45. High impedances can be seen trending to the east. 44
Figure 47: Inversion QC: Comparison of Post-stack seismic, synthetics and residuals. Note that the circled high residual feature is observed close to the underburden boundary. 45
Figure 48: Composite plot inverted facies across the study area. 45
Figure 49: AI-PHIT and AI-PHIE cross-plots. Note the distinct clusters present, which correspond to shaley and sandy intervals. 47
Figure 50: Highlighting the location of the clusters on the Stream-34 well. The red polygon on the AI-PHIT cross-plot highlights shales on he right at the well. 47
Figure 51: Point-density plots of the sandstone AI-porosity transforms. Upscaled log data are shown. 48
Figure 52: Point-density plots of the shale AI-porosity transforms. Upscaled log data are shown. 48
Figure 53: Application of AI-PHIE transforms. In blue we see the transforms applied to the AI log, while in the right-hand track in red we see the transform applied to the Ji-Fi inversion result extracted at the well. 49
Figure 54: Application of AI-PHIT transforms. In blue we see the transforms applied to the AI log, while in the right-hand track in red we see the transform applied to the Ji-Fi inversion result extracted at the well. 50
Figure 55: Application of AI-PHIE transforms in 3D using the Ji-Fi inversion output. 51
Figure 56: Application of AI-PHIT transform in 3D using the Ji-Fi inversion output. 51

Table D.I.5.1-1 Summary of Testing and Monitoring

Activity	Location(s)	Method	Analytical Technique	Lab/ Custody	Purpose
CO_2 STREAM MONITORING					
Carbon Dioxide Stream Analysis	Comingled inlet pipework to Minerva facility	Sampling Port	Standard gas analysis at lab	Provided by lab	Monitor injectate for accounting
INJECTION AND INTEGRITY MONITORING					
Injection Pressure	Distributed meters at MS CCS 1 & 2	Electronic volumetric flow meter with P/T measurement	Direct measurement	NA	Pressure of CO2 stream
Injection Rate	Distributed meters at MS CCS 1 & 2	Electronic volumetric flow meter with P/T measurement	Direct measurement	N/A	Rate of injection
Injection Volume/Mass	Distributed meters at MS CCS 1 & 2	Electronic volumetric flow meter with pressure & temperature (P/T) measurement	Volume measurements	NA	Volume of CO2 distributed to each well; calculation of mass
Annular Pressure/Temperature	Downhole gauge with transmitter at each wellhead	Electronic P/T gauge in the annulus	Direct measurement	NA	Pressure maintenance in tubing-casing annulus
Annular Volume	Downhole gauge with transmitter at each wellhead	Electronic P/T gauge in the annulus	Calculated measurement	NA	Pressure maintenance in tubing-casing annulus
Downhole Pressure/ Temperature	Downhole gauge with transmitter at each wellhead of MS CCS 1 & 2, MS IZ 1	Downhole P/T gauge run on tubing	Direct measurement	NA	P/T downhole near injection zone
Wellhead Pressure	Pressure gauge on the tubing and annulus of MS CCS 1 & 2, MS IZ 1	Surface pressure gauge at the wellhead	Direct measurement	NA	Wellhead pressure safety
External Mechanical Integrity	MS CCS 1 & 2	DTS fiber optic cables installed in the wellbore annulus	Direct Continuous monitoring	NA	Detect fluid or pressure migration from the injection zone and leakage in casing
Wireline Logging	Conducted at each injection well	Injection profile log	Provided by vendor	NA	Demonstrate External Mechanical Integrity
Corrosion Monitoring	Corrosion Loop	Non-Destructive Testing: Ultrasonic and Radiography equipment	ASTM G1-03	NA	Monitor system integrity
SUBSURFACE MONITORING					
Above Confining Zone Monitoring	MS USDW 1 & 2	Water sampling	Laboratory analysis	Provided by lab	Document groundwater chemistry
	MS CCS 1 & 2	DTS fiber optic cables installed along the long-string	Direct measurement	NA	Monitor for fluid migration from the injection zone
Pressure Fall-Off Testing	MS CCS 1 & 2	EPA Region 6 UIC Pressure Falloff Testing Guideline-Third Revision (August 8, 2002)	Direct Measurement	NA	Assess injectivity
Pressure Front Tracking (Direct)	MS IZ 1, MS CCS 1 & 2	Downhole P/T gauge run on tubing	Direct measurement	NA	In-zone pressure tracking
CO_2 Plume Tracking (Indirect)	MS CCS 1	Walk Away VSP	VSP	NA	Defining the edge of the plume and ensuring it remains within the permitted AoR.
	MS CCS 1	Vertical seismic profile (VSP)	VSP	NA	
	MS CCS 1	2D Seismic Lines	2D Seismic	NA	
	MS IZ 1	PN logs	Wireline logging	NA	Monitor carbon dioxide saturation

Table D.I.6-1 Instrumentation Summary

Instrument Type	Monitoring Location	Monitoring Target	Data Collection Location(s)	Explanation
CO_2 STREAM MONITORING				
Sampling port	CO_2 Stream	Monitor injectate for accounting	Collection at sampling port; analysis via lab	Identify unacceptable impurities, CO_2 accounting
INJECTION AND INTEGRITY MONITORING				
Electronic volumetric flow meter with pressure & temperature (P/T) measurement	MS CCS 1 & 2	Monitor injectate for each well	Computerized control system	Injection volume, rate, and pressure (with mass and density calculations) for surveillance and input to models
Wellhead pressure gauge on tubing	MS CCS 1 & 2, MS IZ 1	Pressure in injection well tubing	Manual reading of gauge	Safety and compliance
Wellhead pressure gauge on annulus	MS CCS 1 & 2, MS IZ 1	Pressure in annulus	Manual reading of gauge	Safety and compliance
Annulus pressure & temperature gauge	MS CCS 1 & 2	Pressure and temperature in tubing-casing annulus	Computerized control system	Monitoring, safety, and compliance
Downhole pressure & temperature gauge	MS CCS 1 & 2	Pressure and temperature in injection interval	Computerized control system	Monitoring, safety, and compliance
DTS fiber optic cable	MS CCS 1 & 2	Surface to Total Depth	Computerized control system	Well integrity
Ultrasonic and Radiography equipment	MS CCS 1 & 2	Corrosion of materials of construction	Loop	Safety and compliance, Well Integrity
SUBSURFACE MONITORING				
Dedicated pump & groundwater level monitoring system	MS USDW 1 & 2	Evangeline Aquifer	Environmental data storage	Installed system or relocated to each of the wells
Downhole pressure & temperature gauge	MS IZ 1	Injection Zone – Pressure	Computerized control system	Track lateral pressure front
Pulse Neutron logging	MS IZ 1	Injection Zone - Plume	Wireline Log	Monitor carbon dioxide saturation within the injection zone
DAS fiber optic cable	MS CCS 1	Surface to Total Depth	Dedicated server, designed as part of VSP array	CO2 Plume Tracking
Walk-Away VSP	MS CCS 1	Injection Zone – Plume	DAS in MS CCS 1 Sources along seismic lines in star pattern	Define the edge of the plume and ensure it remains within the permitted AoR.
3D DAS VSP	MS CCS 1	Injection Zone - Plume	DAS in MS CCS 1 Sources along 500 x 500 foot Grid	Define the edge of the plume and ensure it remains within the permitted AoR.
2D Seismic Lines	Surface	Injection Zone - Plume	Sources and receivers along seismic lines in star pattern	Define the edge of the plume and ensure it remains within the permitted AoR.

Table D.I.6.1-1 Summary of Analytical Parameters for CO_2 Stream

Parameter	Analytical Methods[1]
Carbon Dioxide (CO_2)	ISBT[2] 2.0 Caustic absorption Zahm-Nagel ALI method SAM 4.1 subtraction method (GC/DID) GC/TCD
Water (H_2O)	ISBT 3.0
Oxygen (O_2)	ISBT 4.0 (GC/DID) GC/TCD
Nitrogen (N_2)	ISBT 4.0 (GC/DID) GC/TCD
Hydrogen Sulfide (H_2S)	ISBT 14.0 (GC/SCD)
Argon (Ar)	ISBT 4.0 (GC/DID) GC/TCD
Sulfur dioxide (SO_2)	ISBT 14.0 (GC/SCD)
Methane (CH_4)	ISBT 10.1 (GC/FID)
Total hydrocarbons (C_2H_6, C_3H_8+)	ISBT 10.1 (GC/FID)
Hydrogen (H_2)	ISBT 4.0 (GC/DID) GC/TCD
Carbon Monoxide (CO)	ISBT 5.0 (Colorimetric) ISBT 4.0(GC/DID)
Nitrogen Oxides (any (NO_x)	ISBT 7.0 Colorimetric
δC_{13} and C_{14}	Isotope ratio mass spectrometry Measured once and when a significant new source is added. Used for attribution during monitoring.

Table D.I.6.2-1 Summary of Operational Parameters Measured with Continuous Recording Devices

Parameter	Device(s)	Location
Annular Pressure and Temperature	Electronic pressure & temperature (P/T) gauge in the annulus with transmitter at the surface	Downhole gauge with transmitter at the wellhead
Annular Fluid Volume	Fluid level gauge	Annular Fluid Reservoir
	Electronic P/T gauge in the annulus with	Downhole gauge with transmitter at the wellhead
Injection Pressure	Electronic volumetric flow meter with pressure measurement	Meter with transmitter at wellhead
Injection Rate	Electronic volumetric flow meter with rate measurement	Meter with transmitter at wellhead
Injection Volume/Mass	Electronic volumetric flow meter with P/T measurement	Meter with transmitter at wellhead
Downhole Pressure	Downhole P/T gauge run on tubing	Downhole gauge with transmitter at the wellhead
Downhole Temperature	Downhole P/T gauge run on tubing	Downhole gauge with transmitter at the wellhead

Table D.I.6.2-2 Continuous Recording Device Specifications

Parameter	Value
VOLUMETRIC FLOW METER	
Calibrated working flow rate range	1 - 33 ft/s (0.3 -10 m/s)
Initial flow rate accuracy	< ± 0.15% of measured volume
Flow rate resolution	0.01 m/s
Flow rate zero stability	< 0.003 ft/s (0.0009 m/s)
DOWNHOLE PRESSURE AND TEMPERATURE GUAGE (Reservoir & Annulus)	
Calibrated working pressure range	200 - 10,000 psi
Pressure accuracy	±0.015% 1.5 psi (at full scale)
Pressure resolution	0.0001
Pressure drift stability	±0.02% full scale, 2.0 psi/year
Calibrated working temperature range	77 to 302°F (25 to 302°C)
Temperature accuracy	0.27°F (0.15°C)
Temperature resolution	0.0001°F
Temperature drift stability	0.018°F (<0.01°C) per year
Temperature rating	-99.4 to 302°F (-73 to 302°C)
Instrument calibration frequency	Annual
WELLHEAD PRESSURE GUAGE (Tubing & Annulus)	
Calibrated working pressure range	10-20,000 psi
Pressure accuracy	0.05% full scale accuracy
Pressure resolution	0.001
Pressure drift stability	Limit of 5% full scale for pressure stability

Table D.I.6.2-3 Representative Logging and Testing Tool Specifications

Fiber Optic Cable	Maximum acquisition rate	Minimum spatial resolution	Minimum sampling interval	Sensing /Operating temperature range	Maximum distance range
MECHANICAL INTEGRITY MONITORING					
Distributed Temperature Sensing (DTS)	3.3 sec	~3.3 ft (1.0 m)	1.08 ft (.33 m)	0 – 573°F/300°C	~12.5 mi (20+ km)
PLUME MONITORING					
Distributed Acoustic Sensing (DAS)	10 kHz	~4.9 ft (1.5 m)	1.08 ft (.33 m)	0°C to +40°C / 32°F to +104°F	12 – 50 (EBF) mi (20 – 80 (EBF) km)

Log	Logging speed	Vertical resolution	Investigation	Temperature rating	Pressure rating
MECHANICAL INTEGRITY LOGGING					
Noise Log	0.5 sec	16 bit	10 ms	350°F	20,000 psi
Oxygen Activation Log	2 ft/min	Point of Measurement	12 in	350°F	20,000 psi
Casing Inspection Log	160 ft/min	Point of Measurement	5.5-9.425 in	350°F	15,000 psi
Cement Bond Log	Up to 9 m/min (29.52 ft/min)	3 in	Casing & Cement Interface	350°F for 30 min	20,000 psi
Casing Collar Locator Log	45m/min	Point of Measurement	20 in	400°F for 30 min	20,000 psi
PLUME MONITORING					
Pulsed Neutron Capture Log	2 ft/min	Point of Measurement	12 in	350°F	20,000 psi

Table D.I.6.3-1 Groundwater Analysis Parameters and the Analytical Methods

Parameters	Analytical Methods[1]
FIELD MEASUREMENTS	
Dissolved Oxygen (field)	APHA 2005
Specific Conductance (field)	APHA 2510
Temperature (field)	Thermocouple
Water Density (field)	Oscillating body method
Static Water Level	Sounder
pH (field)	EPA 150.1
LABORATORY ANALYSIS	
Cations (Al, Ba, Mn, As, Cd, Cr, Cu, Pb, Sb, Se, Zn, Tl)	SW846 6010/6020
Cations (Ca, Fe, K, Mg, Na, Si)	SW846 6010/6020
Anions (Br, Cl, F, NO3, SO4)	SM 300
Dissolved CO_2	Coulometric titration, ASTM D513-11
Isotopes δ13C of DIC	Isotope ratio mass spectrometry
Dissolved CH_4 (Methane)	SM 6211 B or 6211 C
Hydrogen Sulfide (H_2S)	ISBT 14.0 (GC/SCD)
Total Dissolved Solids (TDS)	Gravimetry; Method 2540 C
Oxygen, Argon, and Hydrogen	ISBT 4.0 (GC/DID) GC/TCD
Alkalinity	Method 2320B

Notes:

[1] Or similar method

- The listed analytical methods may be revised based on input from the laboratories selected to do the work, and field instruments used during a given event.
- Field duplicates to be collected at rate of 10% (1 for every 10 samples) or 1 per event.
- MS/MSDs to be collected at a rate of 5% (1 for every 20 samples) or 1 per event.
- Field blanks and equipment blanks will be collected as per Section 6.3 of the QASP, Appendix I.

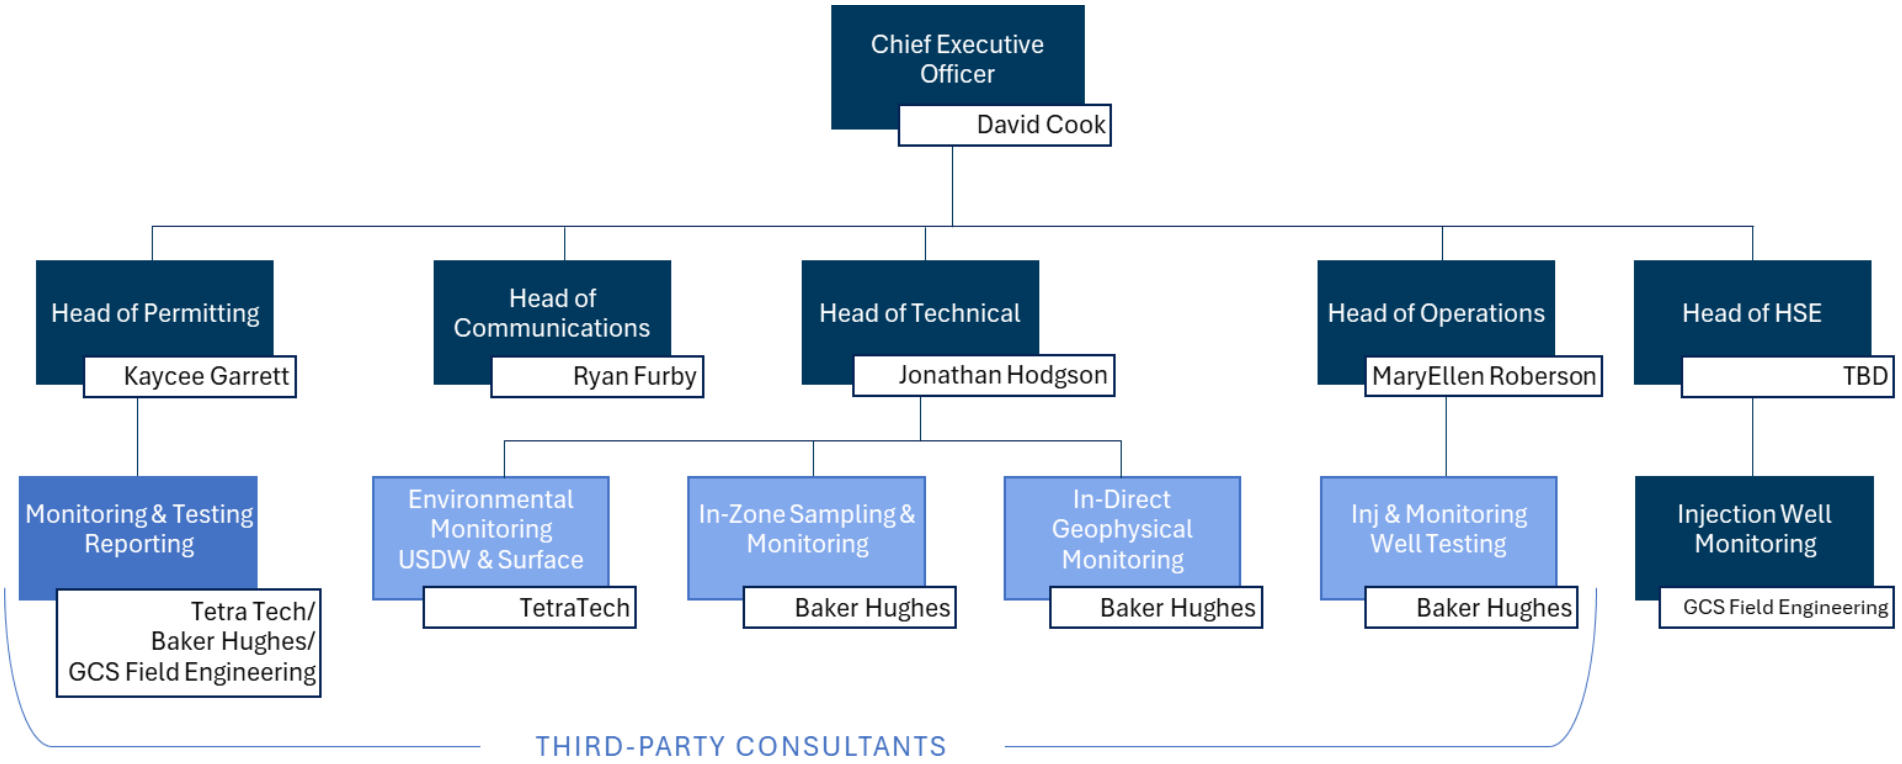

Table D.I.9.4-1 Summary of Analytical Standard Operating Procedures (SOPs)

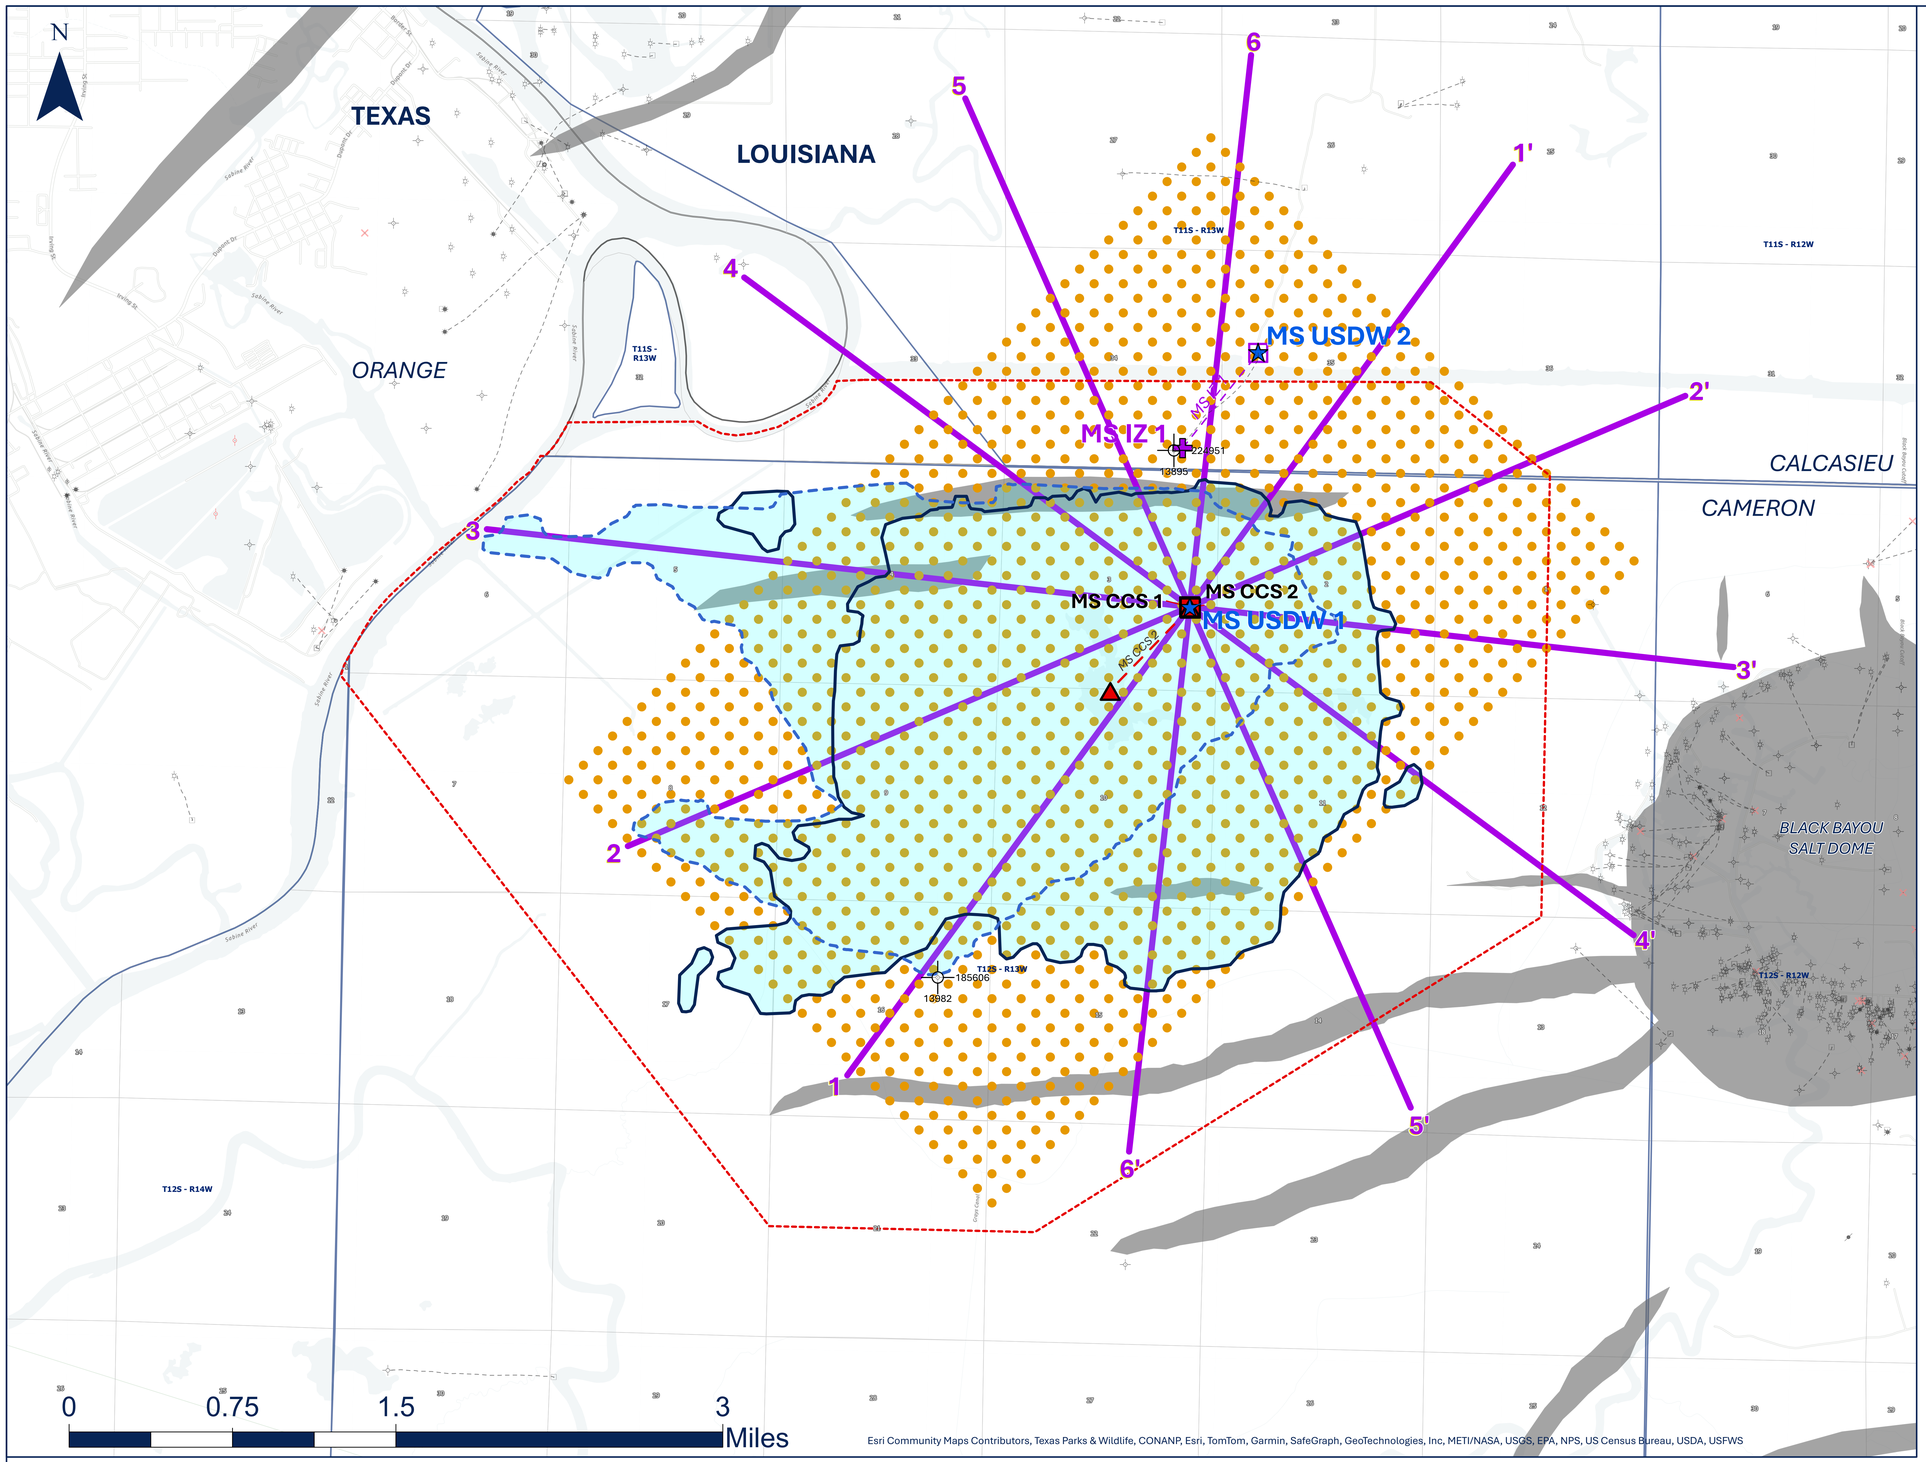

Parameters	Analytical Methods[1]	Detection Limit/ Range	Typical Precisions	QC Requirements
Cations Al, Ba, Mn, As, Cd, Cr, Cu, Pb, Sb Se, & Tl	ICP-MS, EPA Method 6020	0.001 to 0.1 mg/L (analyte, dilution and matrix dependent)	±15%	Daily calibration; blanks, duplicates and matrix spikes at 10% or greater frequency
Cations Ca, Fe, K, Mg, Na, & Si	ICP-OES, EPA Method 6010B	0.005 to 0.5 mg/L (analyte, dilution and matrix dependent)	±15%	Daily calibration; blanks, duplicates and matrix spikes at 10% or greater frequency
Anions Br, Cl, F, NO3, & SO4	Ion Chromatography, EPA Method 300.0	0.02 to 0.13 mg/L (analyte, dilution and matrix dependent)	±15%	Daily calibration; blanks and duplicates at 10% or greater frequency
Dissolved CO_2	Coulometric titration, ASTM D513-11	25 mg/L	±15%	Duplicate measurement; standards at 10% or greater frequency
Isotopes δ13C of DIC	Isotope ratio mass spectrometry[2]	12.2 mg/L HCO3 for δ13C	±0.15‰ for δ13C	10% duplicates; 4 standards/batch
TDS	Gravimetry, APHA 2540C	12 mg/L	±10%	Balance calibration, duplicate analysis
Water Density (field)	Oscillating body method	0.0000 to 2.0000	±0.0002 g/mL	Duplicate measurements
Alkalinity	APHA 2320B	4 mg/L	±3 mg/L	Duplicate analysis
pH (field)	EPA 150.1	2 to 12 pH units	±0.2 pH unit	User calibration per manufacturer recommendation
Specific conductance (field)	APHA 2510	0 to 200 mS/cm	±1% of reading	User calibration per manufacturer recommendation
Temperature (field)	Thermocouple	-5 to 50°C	±0.2°C	Factory calibration

Notes

1 An equivalent method may be employed with the prior approval of the Commissioner.
2 Gas evolution technique by Atekwana and Krishnamurthy (1998), with modifications made by Hackley et al. (2007)

1.0 INTRODUCTION

The *Contract Laboratory Program Guidance for Field Samplers* (also referred to as the *Sampler's Guide*) describes the organizational roles and responsibilities for those who plan and conduct environmental sample collection for analysis through the U.S. Environmental Protection Agency (EPA) Contract Laboratory Program (CLP).

The following lists the sections of this Guide:

- Section 1, *Introduction*, introduces the structure and purpose of this document.
- Section 2, *General Sampling Information*, describes the general activities associated with environmental sampling.
- Section 3, *CLP Statements of Work*, describes the Statements of Work (SOWs) that define the requirements for CLP sampling.
- Section 4, *CLP Sample Documentation*, lists the types of documentation used to track CLP samples.
- Section 5, *The Scribe Documentation Software Tool*, provides information about Scribe, a software tool used to create sample documentation.
- Section 6, *CLP Sample Containers*, describes the types of containers required for CLP samples.
- Section 7, *CLP Sample Collection*, describes the process by which CLP samples are collected.
- Section 8, *CLP Sample Transportation and Shipping*, outlines the requirements for the packing and shipping of CLP samples.
- Section 9, *Sampler Resources*, provides links to additional information for sampling organizations.

The following lists the appendices of this Guide:

- Appendix A, *Functions within a Sampling Project*, describes the functions within a sampling project which are taken from the Quality Assurance Project Plan (QAPP) requirements.
- Appendix B, *General CLP Sample Collection Guidelines for Aqueous VOA Samples*, provides guidelines for Volatile Organic Analyte (VOA) water samples.
- Appendix C, *CLP Sample Collection Guidelines for Soil VOA Samples by SW-846 Method 5035A, TCLP Extraction by EPA SW-846 Method 1311, and SPLP Extraction by EPA SW-846 Method 1312* provides guidelines for VOA soil samples.
- Appendix D, *CLP Sample Collection Requirements by Analysis Type*, contains the sample collection requirements by SOW.
- Appendix E, *Sampling Techniques and Considerations*, recommends sampling techniques.
- Appendix F, *International Shipping*, contains information regarding shipping samples to laboratories outside the United States.
- Appendix G, *Sampling Checklists*, contains checklists used to help the sampler ensure that all necessary steps are completed.
- Appendix H, *Glossary*, provides definitions for terms used in this document.

If the field sampling team is planning to use the CLP, they should use this Guide to develop the Site Project Plan (SPP), QAPP, and Field Sampling Plan (FSP) documents.

1.1 Overview of the CLP

The CLP is a national network of EPA personnel, commercial laboratories, and support contractors whose fundamental mission is to provide environmental sample collection and analysis under the Superfund program. The Superfund program was established under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) of 1980 and presently exists under the Superfund Amendments and Reauthorization Act (SARA) of 1986. The CLP is directed by the EPA Analytical Services Branch (ASB) of the Technology Innovation and Field Services Division (TIFSD) within the Office of Superfund Remediation and Technology Innovation (OSRTI) under the Office of Land and Emergency Management (OLEM).

The primary responsibility of the CLP is to provide analytical data of known and documented quality to CLP customers through its routine and modified chemical analytical services. The CLP provides a framework that allows data to be produced in a cost-effective and efficient manner. In addition, the CLP has established strict Quality Control (QC) procedures and detailed documentation requirements to ensure the consistent quality of the data. Current CLP data users include the EPA Regions, other EPA Headquarters programs, State and Tribal governments, and other Federal agencies.

1.1.1 Key Participants within the CLP Sampling Process

In coordinating Superfund sampling efforts, ASB is supported by the Sample Management Office (SMO) contractor, Regional Sample Control Coordinators (RSCCs), Site Assessment Managers (SAMs), On-scene/On-site Coordinators (OSCs), and Remedial Project Managers (RPMs). Samplers may work directly with the RSCC, and/or an OSC from the Site Support Personnel during a sampling event. Refer to Table 1-1 for a description of the functions performed by key participants (functions may vary by Region).

Table 1-1. Participants in the CLP Sampling Process

Participants	Responsibilities
Analytical Services Branch (ASB)	ASB directs the CLP within the TIFSD of the OSRTI in the OLEM. ASB's responsibilities include: • Development of the SOWs that define required analytical methods (including QC, detection/quantitation limits, and holding times) for the analytical services procured under the CLP • Development and implementation of policies and budgets for Superfund analytical operations • Development of information management policies and products for analytical data • Management of SMO and Quality Assurance Technical Support (QATS) contracts • National administration, evaluation, and management of the CLP • Direction of CLP Quality Assurance (QA) activities in coordination with overall OLEM QA activities To obtain the most current ASB contact list, refer to the following website: https://www.epa.gov/clp/forms/contact-us-about-superfund-analytical-services-or-contract-laboratory-program#tab-2
CLP Sample Management Office (SMO)	The contractor-operated SMO provides management, operations, and administrative support to the CLP. SMO receives Regional analytical requests, coordinates and schedules sample analyses, and tracks sample shipments. SMO also receives and checks data for completeness and compliance, processes laboratory invoices, and maintains a repository of sampling records and program data.

Table 1-1. (Continued) Participants in the CLP Sampling Process

Participants	Responsibilities
CLP Contract Laboratories	The contractor-operated laboratories within the CLP provide analytical services for the separation, detection, and quantitation of the CLP's target analytes.
Environmental Response Team (ERT)	The ERT is responsible for the development, implementation, and management of the Scribe software system. In addition, the ERT oversees the development of Scribe training webinars and on-site training.
Environmental Response Team (ERT) Support Contractors	The ERT Support Contractors provide technical and administrative support for the development, implementation, and management of the Scribe software system. In addition, the ERT Support Contractors support the development of Scribe training webinars and on-site training.
Regional Sample Control Coordinator (RSCC)	In most Regions, the RSCC coordinates sampling efforts and serves as the central point-of-contact for sampling questions and problems. The RSCC works with SMO to request analytical services and receive laboratory assignments. In addition, the RSCC's activities may include informing SMO of sample shipment, cancellations, special instructions, and sampling issues. To obtain the most current RSCC contact list, refer to the following website: https://www.epa.gov/clp/forms/contact-us-about-superfund-analytical-services-or-contract-laboratory-program#tab-3
Site Support Personnel	The Site Support Personnel consist of the EPA personnel and contractors responsible for developing the QAPP and Sampling Plan for the sampling event at the site. It includes such personnel as the sampling team, QA personnel, OSC, SAM, and RPM. In most Regions, the Site Support Personnel develop Standard Operating Procedures (SOPs) for field sampling and related procedures, and assist sampling teams in adhering to the SOPs. The sampling team determines what type(s) of CLP services will be required for a particular sampling event. The Site Support Personnel review Sampling and Analysis Plans (SAPs) prepared by sampling teams and oversee sampling teams in the field. In addition, the state or territorial environmental protection agency for the location of the site provides support for the sampling event.

This page is intentionally left blank.

2.0 GENERAL SAMPLING INFORMATION

2.1 Goals of the Sampling Process

Once the U.S. Environmental Protection Agency (EPA) has determined that physical, chemical, and/or biological testing of a site is necessary, samples of material from the site area must be collected. The type of material that must be collected and the analytical method to be used depends upon the physical location of the site, detection level(s), site history (previous sampling), and known or unknown conditions and contaminants. Samples should be collected according to the approved project and site-specific Quality Assurance Project Plan (QAPP) and Sampling and Analysis Plan (SAP). This Guide does not define specific sampling procedures, as these depend upon individual site conditions, Regional requirements, and acceptance and performance criteria. Since Regions may have their own specific requirements for individual sampling programs, they are responsible for generating Region-specific sampling Standard Operating Procedures (SOPs). EPA personnel shall also follow the procedures in CIO 2105-P-02.0 (*EPA QA Field Activities Procedures*).

2.1.1 Follow the Required Sampling Procedures

It is imperative that samplers be aware of the minimum Contract Laboratory Program (CLP) and Regional requirements that directly impact and define how a sampling event will take place. It is important to note that the procedures and guidelines set forth in this document are considered minimum CLP requirements.

The purpose of sampling is to collect representative portions from a suspected contaminated site. Sample collection is critical to determining the presence, type, concentration, and extent of environmental contamination by hazardous substances; thus, it is a crucial part of every sampling and environmental testing effort. Sampling procedures must be consistently followed to mitigate risk of error and the expense of resampling.

Failure to follow proper sampling and shipping procedures could result in samples that are contaminated, in broken containers, mislabeled, lost during shipping, compromised due to improper preservation, or unusable because of a missed holding time. If procedures are inconsistently or improperly followed, any resultant analytical data may be inaccurate and may not be legally defensible.

2.1.2 Maintain Chain of Custody of Samples and Data

Acquiring accurate and legally defensible data is the CLP's primary objective; therefore, the samplers must collect samples according to strict sampling procedures, plans, and guidelines. The Chain of Custody (COC) Records must be generated and the sample COC maintained. EPA and

many other Federal agencies use data resulting from analytical testing of samples for the following activities:

- Site Characterization
- Source Evaluation
- Identification of Potentially Responsible Parties (PRPs)
- Remedial Design
- Assessment of response and remedial priorities
- Remedial Action
- Remedial Investigation/Feasibility Studies
- Assessment of risk to human health and the environment
- Determination of appropriate cleanup actions
- Determination of cleanup achievements

2.1.3 Field Operation Records

Samplers must maintain complete, accurate, and legible field operations records as they perform a sampling activity. The following records are included:

- Field logbooks
- Corrective Action reports
- Sampling trip reports
- Supplemental standardized forms
- Records such as maps or photographs that document each step of each activity performed in the field

Samplers must refer to their project plans for Region-specific field operations record requirements. These records are an important tool because they are considered a part of the official project file when legal issues arise.

2.1.4 Comply with Safety Procedures

Care must be taken to maintain the safety of personnel collecting and handling CLP samples. If sampling requires digging in soil, utility lines (gas, oil, cable, etc.) must be marked to prevent injury or utility outage. Samples must be handled, packed, and shipped in accordance with all applicable Federal [Occupational Safety and Health Administration (OSHA) and Department of Transportation (DOT)] regulations for hazardous materials. Refer to the Health and Safety Plan (HASP) for detailed site safety requirements.

2.2 Obtain Municipal Permits, Licenses, and Clearances

Before starting a sampling event, samplers must obtain the proper municipal permits, access to the property, and any government clearances, if required. Samplers must also contact any appropriate utility companies to ascertain where any underground pipes, cables, etc., may be located.

2.2.1 Request Access to County, State, Tribal, Military, and/or Federal Property

Proper access to perform sampling activities is important not only for legal reasons, but also to eliminate delays in work and possible refusal to allow sampling to take place. It is crucial that the appropriate permits, licenses, and clearances be secured to obtain access for sampling activities that will be performed on County, State, Tribal, military, and/or Federal property. The sampler must contact the appropriate government offices or personnel well in advance to determine what kinds of approval are required. Pre-approval may be required for specific types of sample collection such as drilling or excavation. For example, drilling on a military base requires pre-

approval. Base security may require clearances for all members of the sampling team, including subcontractors. This process may take two or more days.

2.2.2 Contact Private Property Owners

Samplers must obtain written permission from the private property owner(s) before sampling on his/her property, even if verbal permission has been granted. It is recommended that samplers obtain verbal permission prior to their arrival at the sampling location, but written permission can be obtained on the day of sampling. If a property owner refuses to grant access to his/her property, it may be necessary for the sampling organization to contact the appropriate authorities for assistance. A sampler who enters private property without permission may be subject to a charge of trespassing, and samples may be considered part of an illegal search and invalid for legal proceedings.

2.2.3 Contact Utility Companies

The sampler must contact local utility companies (e.g., power, phone, gas, cable, sanitation, etc.) at least one week prior to the sampling event to have underground cables, lines, and pipes flagged and marked. This is required by law. A national one-call directory can be found at: https://call811.com

It may be necessary to turn off the utilities (i.e., electrical wires or gas lines) in order to obtain samples. The utility service(s) disruption dates should be confirmed at least two days prior to sampling activities. Samplers should follow Regional or other appropriate program procedures for the disruption of utilities.

Pre-payment of survey fees to local utility companies may be required.

2.3 Analytical Services Request

To prepare for the sampling event, the samplers should review the “Analytical Services Request Regional Notification” for samples from the CLP. This information may be in the form of the “Analytical Services Request Regional Notification” obtained from the Sample Management Office (SMO) Contract Laboratory Program Support System (CLPSS) Portal, supplied by the Regional Sample Control Coordinator (RSCC), or in other forms of communication from the Region. Information for Modified Analyses may also be obtained from the SMO CLPSS Portal. Field team leaders should contact their RSCC, Remedial Project Manager (RPM), or On-Site Coordinator (OSC) to review this information prior to going into the field, and ensure that this information matches information in the Site Project Plan (SPP), SAP, and/or QAPP. An eXtensible Markup Language (XML) file is provided as part of the laboratory assignment from the SMO CLPSS Portal which can be used for uploading site information into Scribe.

Review the following sources of information for planning:

- **Sample information:** Provides the number of samples requested, the sample matrix, the analysis types, and if Preliminary Results are required. This information is used to determine the equipment and supplies needed for the sampling event.
- **Site location:** Determines whether there are any specific requirements for accessing/exiting the site, or for working at the site.
- **Shipping period:** Establishes the time frame during which the samples are to be shipped to the laboratory/laboratories. This helps determine when sampling should occur.
- **Laboratory information:** Specifies where the samples will be shipped.

2.3.1 Review Sample Request

Review the "Analytical Services Request Notification" and other Regional communication for the following information:

- ☐ The sample request determines some of the preparatory activities for the sampling event.
- ☐ Review and evaluate the sample request to determine the number and types of samples to be collected.
- ☐ Review the required sample collection method(s).
- ☐ Review decontamination procedures necessary for site.
- ☐ Make note of sample holding times and conditions.
- ☐ Determine Performance Evaluation (PE) and Quality Control (QC) sample requirements.
- ☐ Determine whether shipping container temperature blanks are required.

2.4 Review Project Plans

Project plans describe, in detail, the requirements for the sampling event. All field team members should be familiar with the applicable project plans prior to beginning field sampling. These plans may include the following documents.

2.4.1 Site Project Plan (SPP)

The SPP describes the requirements for any activity taking place at the site. It contains information such as site history, potential contaminants, topographical information, etc. that may be integrated into the QAPP.

2.4.2 Health and Safety Plan (HASP)

The HASP describes the measures necessary to maintain the health and safety of the sampling team during the sampling event. It can include topics such as the following:

- Organization structure
- Job hazard analysis
- Site control
- Training
- Medical surveillance
- Personal protective equipment (PPE)
- Exposure monitoring
- Thermal stress
- Decontamination
- Emergency response
- Location of and directions to the nearest Emergency Room or hospital
- Standard Operating Procedures
- Confined space operations
- Spill containment

2.4.3 Quality Assurance Project Plan (QAPP)

The QAPP describes the data quality objectives and data requirements for the project, and is used by samplers to develop any subsequent plans such as the SAP or the Field Sampling Plan (FSP). Refer to Appendix A for more information on QAPP sampling requirements.

2.5 Assemble Sampling Materials

Samplers should prepare for a sampling project by assembling the appropriate sampling materials (equipment, supplies, sample containers, packing materials, and shipping materials). The equipment and supplies must be properly cleaned, calibrated, and tested as necessary to meet the needs of the sampling project prior to sampling.

2.5.1 Equipment and Supplies

Samplers should review the project plans to determine the equipment necessary for sample collection.

The following should be obtained prior to a sampling event:

- Sample containers
- Shipping containers
- Packing material
- Reagent water for decontamination and for preparation of field/equipment blanks
- Access to the Scribe software for creating sample labels, stickers, Traffic Report/COC (TR/COC) Records, and Region-specific Scribe templates
- Custody seals
- Sampling equipment such as bowls, augers, pumps, etc.
- PPE
- Internet access (either at the time of sampling or soon after the samples are shipped)

The QAPP, the SAP, or the CLP Statement of Work (SOW) may also require field samplers to provide the following:

- Shipping container temperature blanks
- Trip blanks for Volatile Organic Analyte (VOA) analysis
- Preservation supplies (e.g., ice or acid)
- Specially prepared sample vials or bottles (e.g., VOA or hexavalent chromium)
- Utensils or equipment for handling tissue samples requested by Modified Analysis

2.6 Perform Readiness Review/Dry Run

A readiness review/dry run is a test run of the proposed sampling event. It is a recommended practice as it affords samplers a chance to review all plans, documentation software (i.e., Scribe), and equipment lists for accuracy and completeness prior to sampling activities. It also provides an opportunity to consult with sampling team members to make sure that all the elements are in place and that everyone understands their tasks before actually going out into the field. Sampling project managers should provide the readiness review or dry run dates and schedules to samplers so that they can prepare accordingly.

2.7 Assess the Status of the Site and the Team

Samplers should consider taking the following actions prior to starting a sampling event:

- ☐ Communicate personnel roles and lines of authority.
- ☐ Verify that HAZWOPER training is up to date for all field staff as required.
- ☐ Ensure that permission has been granted to enter the site and collect samples.
- ☐ Confirm that utility work has been completed (if required).
- ☐ Review local weather forecast to be aware of possible dangerous weather conditions. Ensure that sampling staff are prepared for weather conditions.

- ☐ If the sampling location is inaccessible, contact the appropriate field or Regional personnel for instructions.
- ☐ Verify that the correct sampling equipment is on site.
- ☐ Ensure that personal safety measures are in place.
- ☐ Ensure that a site HASP is in place and includes procedures for emergency medical treatment and first aid, evacuation procedures, emergency contacts, and location of emergency medical facilities.
- ☐ Identify and mark the sampling location with buoys, flags, or stakes according to the sampling plans, maps, and grids.
- ☐ Park the car/van away from the sampling site and turn off the engine. Be aware of car exhaust (BTEX) contamination to volatile organic samples through all procedures, including loading and unloading the containers during shipping.

2.8 Initiate Site Control Measures

The sampling team is responsible for implementing the necessary site control measures during the sampling event, which may include the following:

- ☐ Maintaining a log of authorized personnel entering the site.
- ☐ Preventing unauthorized persons from entering the site.
- ☐ Ensuring that any decontamination equipment or procedures to prevent sample cross-contamination required in the QAPP and/or FSP are in place and carried out.

2.9 Maintain Field Logbook

Samplers must maintain a field logbook that documents the field activities. The information in the field logbooks may be used as evidence in court. The field logbook should meet the following criteria:

- ☐ Use waterproof ink to record all entries.
- ☐ Record the date and time of all entries, and the name of the person recording the information.
- ☐ Correct all errors by drawing a line through the error, initialing and dating the error, and then adding the correct information.
- ☐ Document sampling project information such as:
  - Project name, Project ID, and location
  - Names of samplers
  - Geological observations, including maps and Global Positioning System (GPS) information
  - Atmospheric conditions
  - Field measurements
  - Sampling dates, times, locations, and sample location coordinates
- ☐ Record sampling activity information such as:
  - Sampling dates and times
  - Name(s) of person(s) recording the information
  - Sample identifications
  - Sample matrices
  - Sample descriptions (e.g., odors and/or colors)
  - Number of samples collected
  - Sampling methods/equipment
- ☐ Record any and all deviations from the sampling plan.
- ☐ Record any and all difficulties in sampling and/or any unusual circumstances.

2.10 Preventing Errors

Errors in the sampling process can result in additional costs and delayed sampling results. The following section lists some of the steps that can be taken to avoid common sampling errors.

Document samples correctly:

- ☐ Use the CLP Sample Number and SMO CLPSS Portal-generated CLP Case Number correctly (sample number on each sample).
- ☐ Submit the signed TR/COC Record with the sample(s).
- ☐ Ensure that the TR/COC Record and the sample container information match each other and are accurate.
- ☐ Accurately and legibly complete and attach a custody seal to each shipping container. The project QAPP may also require that custody seals be attached to each sample container or plastic sample bag. Refer to the project QAPP for specific instructions.

Collect and preserve samples correctly:

- ☐ Collect a sufficient volume of sample so that the laboratory can perform the requested analysis and quality controls, such as Matrix Spike (MS), Matrix Spike Duplicate (MSD), and laboratory Duplicate.
- ☐ Ensure that required preservatives have been added to samples.

Ship samples correctly:

- ☐ Pack bottles and containers to prevent breaking or spilling during shipping.
- ☐ For iced samples, evenly distribute bags/packets of ice throughout the cooler and between the sample containers to ensure that all samples are sufficiently cooled to a temperature of $\leq 6°C$, but not frozen, and include a sealed container of water to be used as a temperature blank.
- ☐ Verify that the TR/COC Records have been included prior to sealing the shipping container.
- ☐ Verify that custody seals are attached to the shipping containers.
- ☐ Ensure that the shipping containers are labeled with the designated laboratory address.
- ☐ Include shipping information for United States Department of Agriculture (USDA) Quarantine samples if applicable.
- ☐ If samples are to be shipped internationally, assemble the required additional paperwork or customs authorizations. Refer to Appendix F, International Shipping, for additional information.
- ☐ Upload the electronic TR/COC Record as soon as possible after shipping.

Communicate effectively:

- ☐ It is extremely important that all parties involved in a sampling event remain in contact during the sampling process.
- ☐ The key elements of communication for a sampling event include the relationship between the RSCC, SMO, the samplers in the field, and the laboratories that will be accepting the samples.
- ☐ In instances where there are any changes to the sampling event due to a cancellation or an increase or decrease in the number of samples to be shipped, the sampler should contact the RSCC as soon as possible. The RSCC will work with SMO to resolve any potential capacity, availability, or overbooking issues with the CLP laboratories.

2.11 Exiting the Site

The following activities should be performed before leaving the sampling site:

- ☐ Ensure that all equipment has been collected and removed.
- ☐ Follow Regional guidance regarding decontamination and doffing of PPE, if used.
- ☐ Follow Regional guidance for waste removal and disposal.
- ☐ Ensure that all sampling personnel have cleared the site.
- ☐ If sampling on private property, provide a sample receipt to the property owner for all samples collected and removed from the site.

3.0 CLP STATEMENTS OF WORK

The overall requirements for sample collection, analysis, and handling under the Contract Laboratory Program (CLP) are described in the CLP Statements of Work (SOWs).

3.1 The CLP SOWs

The CLP SOWs are available on the U.S. Environmental Protection Agency (EPA) website at: https://www.epa.gov/clp/superfund-clp-analytical-statements-work-sows. Table 3-1 lists the CLP SOWs.

Table 3-1. CLP Statements of Work

Statement of Work	Analysis Types	Matrix Types
High Resolution	Chlorinated Dibenzo-*p*-Dioxins (CDDs) and Chlorinated Dibenzofurans (CDFs) Chlorinated Biphenyl Congeners (CBCs)	Soil, sediment, biosolids, oil, sludge, ash, tissue, water, and wipe
Organic/Inorganic	Trace Volatile Organic Analytes (Trace VOAs) Trace VOAs Selected Ion Monitoring (SIM) Volatile Organic Analytes (VOAs) Semivolatile Organic Analytes (SVOAs) SVOAs SIM Pesticides Aroclors Metals by Inductively Coupled Plasma - Atomic Emission Spectroscopy (ICP - AES), Inductively Coupled Plasma - Mass Spectrometry (ICP-MS) Mercury by Cold Vapor Atomic Absorption (CVAA) Spectrometry Cyanide by Spectrophotometry Anions by Ion Chromatography (IC)* Hexavalent Chromium by IC* Total Organic Carbon (TOC)*	Soil, sediment, water, Toxicity Characteristic Leaching Procedure (TCLP)/ Synthetic Precipitation Leaching Procedure (SPLP) leachate , waste, and wipe

*Anions, Hexavalent Chromium, and TOC will be available by Modified Analysis (MA).

3.2 CLP Sample Definition

A CLP sample is defined as a discrete portion of material to be analyzed from one location for each individual or set of analyses.

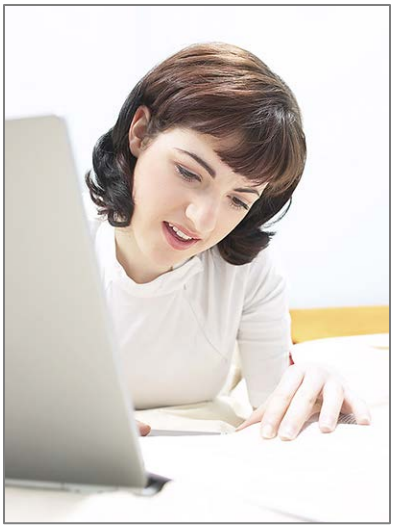
A sample consists of all sample aliquots (portions), provided that the analyses are all requested from the same CLP analytical program:

- for each individual or set of analytical methods
- from one location
- for one sample matrix
- for one laboratory

3.2.1 Mixed-matrix Samples

In some instances, a mixed-matrix sample which contains either a supernate (for a sediment/soil sample) or a precipitate (for a water sample) may be collected. The decisions made with regard to the different matrices in such samples can have profound impacts on data usability. In this event, samplers should consult their sampling plans and/or discuss the required procedures with the Remedial Project Manager (RPM), On-Site Coordinator (OSC), or designee.

In general, it is recommended that two individual samples be collected by separating the aqueous layer from the solid/precipitate layer at the point of collection if possible. If the phases or layers cannot be separated effectively in the field at the point of collection, direction should be provided to the receiving laboratory to separate the layers under controlled conditions. In this case, additional sample numbers will be needed for the separate phases. They should be assigned two different sample IDs (e.g., Sample IDs ABC124 and ABC125 for Sample ID ABC123), along with notes in the field sample log and in the Special Instructions section of the Chain of Custody (COC) Record, indicating that the sample IDs are derived or related to the same sample. Refer to Section 5.1.5, Using Scribe for Mixed-matrix Samples, for information on how to use the Scribe software to track mixed-matrix samples.



When samples are collected from several locations to form a composite sample, the sample should be assigned either a number from one of the locations used during collection, or a unique number that represents the composite sample, for tracking purposes. The numbering scheme used internally at a sampling event for identifying composite samples should also be documented appropriately (e.g., in the field logbooks).

3.3 CLP Analyses

CLP analysis is generally used for Superfund sites and includes the target analytes. The matrices can be water, leachates derived from the TCLP or SPLP, soil, sediment, waste, wipe, or tissue (non-human) for high resolution analyses. Additional matrices requested under Modified Analysis (MA) for inorganics and organics may include oil, sludge, ash, construction waste, biosolids, or tissue (non-human).

4.0 CLP SAMPLE DOCUMENTATION

The U.S. Environmental Protection Agency (EPA) Contract Laboratory Program (CLP) is required to produce accurate and legally defensible data. Therefore, in order to produce legally defensible data, control of the samples must be maintained to ensure that the samples accurately represent the site and location from which they were collected. Sample documents are tools that allow EPA to maintain the chain of custody of the samples from collection, through shipping, to analysis. The documentation also associates the sample to the sample data. Samplers should review their site-specific project plans and Quality Assurance Project Plans (QAPPs) to determine other types of documentation that must be completed for a sampling project. The following section describes the documents used to maintain the chain of custody and the tools used to create these documents.

The following table summarizes CLP sample documentation.

Table 4-1. CLP Sample Documentation Tracking

Type	Source	Purpose
CLP Sample Number	Assigned by sampling software (Scribe); ranges are supplied by the Regional Sample Control Coordinator (RSCC)	Identifies sample data. Associates the sample to the sample data.
CLP Case Number	Generated by the Sample Management Office (SMO) Contract Laboratory Program Support System (CLPSS) Portal	Identifies groups of samples collected during a single sampling event.
Traffic Report/Chain of Custody (TR/COC) Record	Created in Scribe	Tracks chain of custody of the sample and sample data.
Custody seals	Supplied by the RSCC or field sampling team	Maintains sample integrity; may indicate sample tampering or contamination if broken.
Sample labels	Created in Scribe	Affixed to the sample container to identify an individual sample.
Field operations records (as necessary)	Created and maintained by sampling team	Maintains a record of activities at the site.
Shipping container label (to the laboratory)	Carrier standard form	Used by the carrier to ship the samples to the laboratory.
Shipping container return label (return from the laboratory)	Carrier standard form	Used by the carrier to have the laboratory return the container to the Region.

The documentation required by a Region for a sampling event is outlined in project plans such as the QAPP, Sampling and Analysis Plan (SAP), and Field Sampling Plan (FSP).

EPA recommends that a dedicated field team member be responsible for all sample documentation steps, including reviewing laboratory scheduling information, creating sample labels and TR/COC Records in Scribe, maintaining a field operations log, and relinquishing control of the samples to the laboratory. This person should be identified in the Site Project Plan (SPP) or QAPP.

Under no circumstances should the site name or address appear on any documentation that is sent to the laboratory (for the CLP).

4.1 CLP Sample Numbers

A sample number is a number that is unique per sampling location and identifies each CLP sample. It is used to track samples throughout the sampling and analytical processes, and is recorded on several types of sample and sample documentation (e.g., TR/COC Records and sample labels).

Table 4-2. CLP Sample Number Letter Codes

Region	Letter Code
1	A
2	B
3	C
4	D
5	E
6	F
7	G
8	H
9	Y
10	J

According to the CLP guidelines, each individual inorganic water sample may be analyzed for total metals or filtered metals, but not both. Therefore, water samples collected for total metal and filtered metal analyses from the same sampling location must be assigned separate and unique CLP Sample Numbers. Samples for Toxicity Characteristic Leaching Procedure (TCLP) and Synthetic Precipitation Leaching Procedure (SPLP) may also require separate CLP Sample Numbers.

4.1.1 Requesting Sample Numbers

CLP Sample Numbers are created in Scribe with ranges supplied by the RSCC. The sampler should request a range of sample IDs from the RSCC. Once the initial number is entered into Scribe, the software will auto-generate the additional sample numbers required for the project. Do not re-use CLP sample numbers, as this may create difficulties for Laboratory Information Management Systems.

4.2 CLP Case Numbers

SMO CLPSS Portal-generated Case Numbers are used to track groups of samples from a sampling event throughout the sampling and analytical processes, and are recorded on several types of sample and sample documentation (e.g., TR/COC Records, sample labels). Samplers should correctly assign the Case Number to the appropriate sample bottle or container. CLP Case Numbers are obtained from the “Analytical Services Request Regional Notification” in the Access Assignment Information task in the SMO CLPSS Portal. Samplers should correctly assign the Case Number to the appropriate sample bottle or container.

4.3 CLP TR/COC Records

A TR/COC Record is used as physical evidence of sample custody and as a permanent record for each sample collected. A chain of custody record documents the exchange and transportation of samples from the field to the laboratory.

To meet CLP sample documentation and chain of custody requirements, samplers must attach a separate, signed TR/COC Record to each container shipped. The sampler should consider TR/COC documentation needs when shipping directly from the site.

- ☐ The TR/COC Record must document each sample within the shipping container.
- ☐ The Carrier Name and Airbill Number should be on each COC.
- ☐ Each TR/COC Record **must be signed by the designated field sampler**, documenting that they have relinquished control of the samples.
- ☐ TR/COC Records should be separated and shipped in the containers with the samples listed on them. Attach the TR/COC Record to the inside of the lid of the shipping container. Samples may not be shipped in a container without the corresponding TR/COC Record. This practice maintains the chain of custody for all samples in case of incorrect shipment.
- ☐ The electronic TR/COC Record should be uploaded as soon as possible after shipping.

If more than one TR/COC Record is used for the samples within one shipping container, all of the records must have complete header information and original signatures. Samplers are responsible for the care and custody of samples from the time of collection to the time of shipment to the laboratories for analysis. A sample is considered under custody if the following conditions are met:

- It is in possession or in view after being in possession
- It was in possession and then secured or sealed to prevent tampering
- It was in possession when placed in a secured area

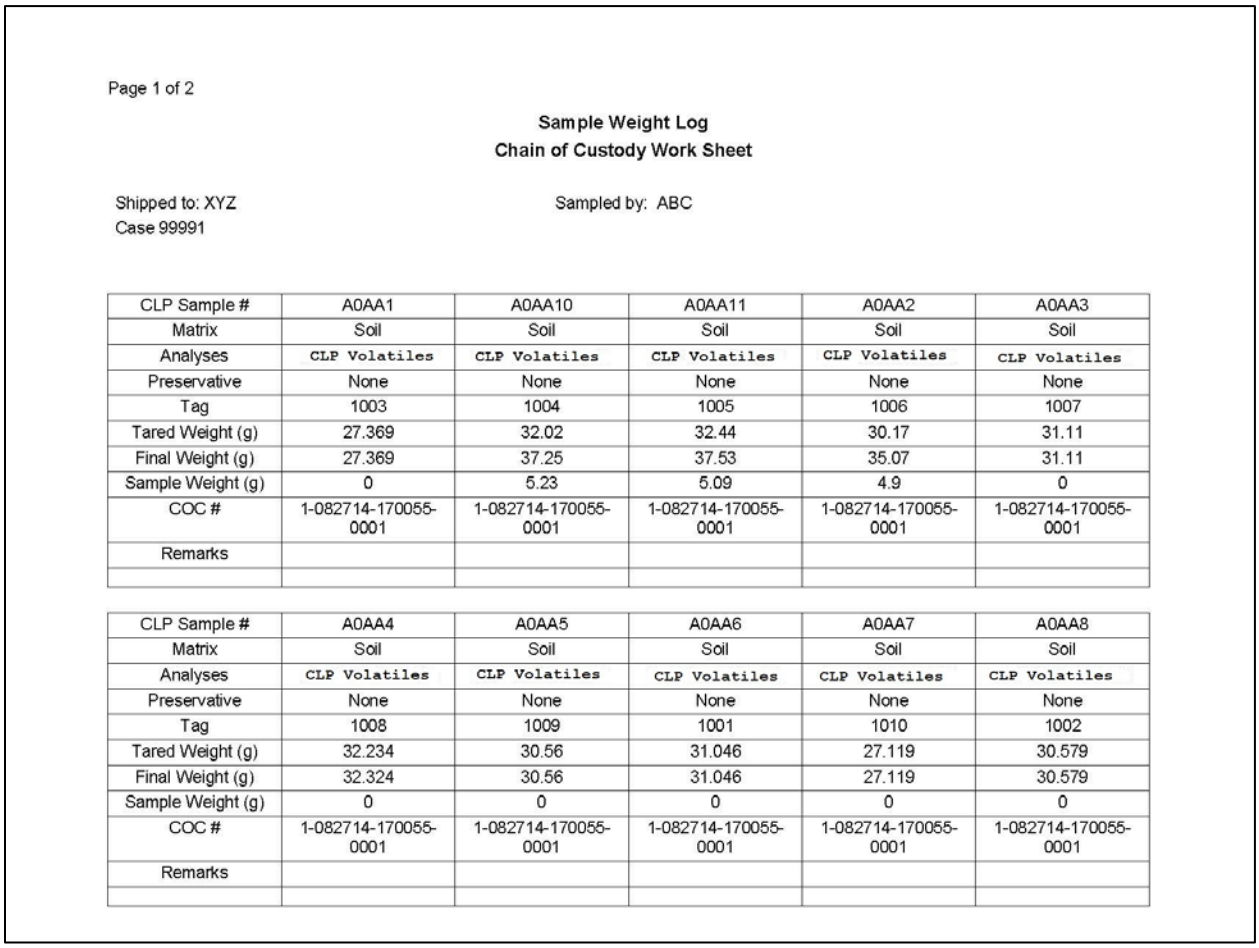
Each time the custody of samples is turned over to another person, the TR/COC Record must be signed off by the former custodian and accepted by the new custodian.

4.4 Chain of Custody Seals

A chain of custody seal is any adhesive label or tape that can be used to seal a sample bottle, container, plastic bag, or shipping container. In the event that a container is opened or tampered with, the seal will be broken. The custody seal is used to maintain the chain of custody, as well as guard against possible sample contamination or tampering during shipping.

- ☐ Custody seals must be placed on each shipping cooler or container, and if required by the project's QAPP or FSP, on each sample bottle, container, or bag (as appropriate).
- ☐ The CLP does not provide custody seals. Custody seals should be obtained from the RSCC or supplied by site personnel.

4.5 Sample Labels



A sample label is a sticker that is attached to a sample bottle or container that contains a field sample or quality control (QC) sample.

- ☐ Sample labels are affixed to each sample container as samples are collected in the field or prior to going in the field.
- ☐ A sample label must contain, at a minimum, the sample number so that the sample can be associated with, and listed on, the associated TR/COC Record.

- Sample labels should also include the required analysis, CLP Case Number, and preservative used (to eliminate confusion at the laboratory). Samplers should refer to their site-specific project plans for Region-specific sample label requirements.
- Site information (e.g., address, site ID) should not be included on the sample label or container.
- Sample tags are NOT required by the CLP.

4.6 Sample Weight Logs

A sample weight log (Figure 4-1) identifies the tared, sample, and final weights per bottle for soil samples for Volatile Organic Analyte (VOA) analysis. In order to support the SOW requirements for VOAs, samplers should enter tared and final weights per bottle in the sample weight log. Sample weight logs are mandatory for VOA soil samples.

Figure 4-1. Scribe Sample Weight Log

5.0 THE SCRIBE DOCUMENTATION SOFTWARE TOOL

The U.S. Environmental Protection Agency (EPA) Analytical Services Branch (ASB) requires samplers to use the Scribe software to create documentation for all Contract Laboratory Program (CLP) sampling efforts. The EPA recommends that a dedicated member of the sampling team be trained in the Scribe software, and be responsible for all uses of Scribe including the sample labels and the Traffic Report/Chain of Custody (TR/COC) Records at the sampling location. For assistance with obtaining or using the Scribe software, contact the Environmental Response Team (ERT) Software Support Help Desk at 800-999-6990 from 9:00 AM – 5:00 PM ET. For additional information regarding Scribe use and training materials, refer to the following website: https://response.epa.gov/scribe. Scribe allows users to create one or more sampling projects, enter data, and create sample documents for that project. Some of the capabilities of Scribe include:

- Tracking sample numbers and Case Numbers
- Associating analysis information to sample numbers
- Creating sample labels
- Setting label size and printing labels
- Selecting sample numbers to add to the chain of custody record
- Printing chain of custody records
- Filtering lists of samples
- Exporting sample data in the following formats: text file (.txt, .csv), spreadsheet (.xls, .wb3), HTML (.htm), XML (.xml), or QuickMap (.kml, .kmz)

The Scribe software tool allows users to track samples electronically. It can be downloaded at no charge from the EPA On-Scene Coordinator (OSC) website at https://www.ertsupport.org/downloads.htm

5.1 Setting Up a Sampling Event in Scribe

Scribe allows the sampler to enter much of the information prior to the event in order to facilitate processing on the day of the event. The following sections describe how to set up the sampling event in Scribe.

5.1.1 Set Up Project

The initial step when using Scribe is to set up the project as follows:

- ☐ Access the Scribe **New Project Wizard** to set up the sampling project.
- ☐ Enter the project **Site Name**, **Site #**, and **Region #** (required).
- ☐ Enter additional project information, if available. The eXtensible Markup Language (XML) file for the Case can be imported from the Sample Management Office (SMO) Contract Laboratory Program Support System (CLPSS) Portal and will customize the analysis and lab lists.

5.1.2 Create Analysis Types

The analysis types to be used for the sampling event must be defined for the project. Refer to the site sampling plan to determine which analyses are to be used.

- Use the **Analyses** table to display a list of all the analysis types available.
- Only analyses with the Program Type of "CLP," such as "CLP ICP-AES Metals," or "CLP Semivolatiles" should be selected for CLP Cases.
- If the required analysis type is missing, it can be added manually using the **Add** button.

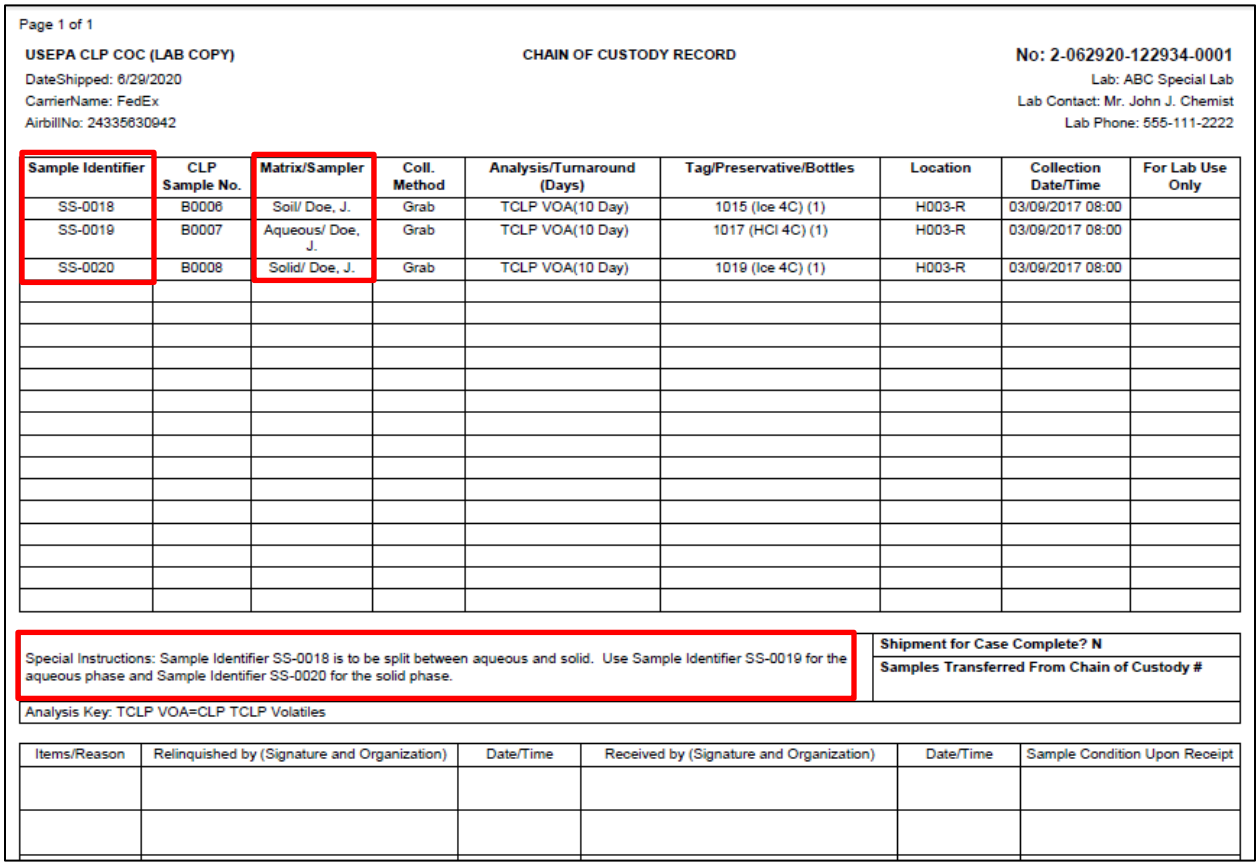
5.1.3 Set Default Sample Number Information

Set up the default values for sample number. This allows the samplers to let the system increment sample numbers, rather than hand entering each one.

- Select **File→Options→CLP/Tag Settings** to display the **CLP/Tag Settings** window.
- Enter the new default values and click **OK**.

5.1.4 Indicate Modified Analysis (MA) on Scribe COC Records

When completing a TR/COC Record in Scribe, indicate an MA as follows:



- Identify the samples that will be analyzed using (a) CLP MA(s) by creating a new analysis within the Scribe Analyses table or at the time of entering the Analyses for the sample.
- The MA analysis should contain the Modification Reference Number within the name assigned to the analysis. For example, if a Region submits an MA for an additional analyte, and the SMO assigns the Modification Reference Number 3001.0, the Scribe Analyses could be named "CLP VOA by MA 3001.0.". The associated abbreviation for this analysis could be "VOA MA".

5.1.5 Using Scribe for Mixed-matrix Samples

The Scribe **LinkSampleNo** field links the original sample to the split samples and numbers. Use this field to link to the sample IDs used for the different sample phases as follows:

- Add two (2) additional samples in Scribe indicating in the matrix field which one is the liquid/aqueous phase and which one is the solid phase (i.e., ABC124 and ABC125).
- Tie the two additional samples to the original sample number using the "LinkSampleNo" field.
  - **In Scribe**, in the **Samples** tab, click the **View** button; the **Select Columns** drop-down menu displays. Put a checkmark next to **LinkSampleNo** to make that column visible.
  - Add the "parent" or the original field sample # in the **LinkSampleNo** column (i.e., ABC123).
  - **On the COC Record**, indicate in the **Special Instructions** which of the two new sample numbers the laboratory is to use for the liquid/aqueous phase and which sample number is to be used for the solid phase.

An example of a Scribe COC Record with mixed-matrix samples is shown in Figure 5-1.

To avoid issues with interpretation, ensure that Total Metals and Dissolved Metals are labeled with separate sample IDs.

This page is intentionally left blank.

6.0 CLP SAMPLE CONTAINERS

The analytical protocol(s) for sample analysis often requires the use of a specific type of sample container. The type of container will also depend on the sample matrix.

It is recommended that samplers use borosilicate glass containers which are inert to most materials when sampling for pesticides and/or other organics, and for Total Organic Carbon (TOC). Borosilicate glass is also recommended for sampling soils for metals. Conventional polyethylene is recommended when sampling for metals and anions in water because of the lower cost and absorption rate of metal ions.

Have extra containers readily available for each sampling event in case of breakage, loss, or contamination.

Containers procured for a sampling event are usually pre-cleaned and shipped ready for use from the manufacturer to the sampling site. Regardless of the type of container used, samplers must ensure that the containers have been analyzed or certified clean to levels below concern for the project based on the specifications in the Quality Assurance Project Plan (QAPP). Certificates must be kept on record. These containers must meet the U.S. Environmental Protection Agency (EPA) container type specifications listed in Tables D-1 through D-4 in Appendix D.

Samplers should document the lot numbers for every lot of cleaned containers used for each project and maintain corresponding certificates of analysis on file and available upon request.

This page is intentionally left blank.

7.0 CLP SAMPLE COLLECTION

Samplers should determine the types of samples or aliquots to be collected, the volume required for each aliquot, and the preservation requirements by referring to the Site Project Plan (SPP) and Contract Laboratory Program (CLP) sample requirements tables in Appendix D. The following sections describe the types of samples that may be required to be collected.

7.1 Requesting the Scheduling of the Laboratory

Samplers must request that the Regional Sample Control Coordinator (RSCC) schedule the laboratory to be used for the analysis. This should be done as far in advance of the sampling event as possible.

- If one or more Modified Analysis (MA) will be required, scheduling requests should be submitted at least four weeks prior to the start of the sampling event to allow the solicitation process to be completed.
- Samplers should provide information regarding the number of samples, analyses, etc. and if Saturday delivery is likely. If known, additional information regarding weekly shipping frequency is helpful to include.
- When scheduling a sampling event that will last for more than one week, it is recommended that the sampler contact the RSCC (or designee) on a weekly basis to provide updates. Communication between the sampler, the RSCC (or designee), and the Sample Management Office (SMO) is important as it ensures better availability of laboratory capacity.
- If the time frame or number of samples for a sampling event changes, the RSCC and SMO should be notified as soon as possible to maintain capacity at the scheduled laboratory.
- The Region should contact the Analytical Services Branch (ASB) in advance if it is suspected that the samples may contain asbestos.

The CLP has the capability to schedule sampling on an emergency basis; however, the sampler must contact the RSCC (or designee) to obtain details regarding how to handle such a situation.

7.2 Preparing for the Shipping of Samples

Once the samples are collected, they will be shipped to the CLP laboratory for analysis. Samplers must have the necessary shipping supplies on site.

7.2.1 Procure Shipping Supplies

Samplers should refer to the appropriate project plans to determine the types of samples that will be collected during the sampling project to determine the necessary packaging materials to have at the site for all pertinent sample container types and sample matrices.

Samplers should also obtain the appropriate shipping paperwork (e.g., shipping forms required by the delivery service).

The CLP strongly discourages the use of vermiculite and cat litter as sources for packing material. These materials interfere with labeling and documentation and are difficult to remove from sample containers and shipping containers.

7.2.2 Laboratory Assignment Notification

Prior to beginning fieldwork, the samplers may either download an "Analytical Services Request Regional Notification" file via the Access Assignment Information task in the SMO Contract Laboratory Program Support Services (CLPSS) Portal, or obtain it from the RSCC.

The "Analytical Services Request Regional Notification" applies only to activities being performed under the CLP Statements of Work (SOWs).

7.2.3 Verify Laboratory Shipping Information

Samplers should verify the laboratory contact information, including the following:

- Laboratory name
- Laboratory address
- Contact name
- Laboratory phone number

This information, which is provided on the "Analytical Services Request Regional Notification", is used to complete both the Traffic Report/Chain of Custody (TR/COC) Records and shipping paperwork such as address labels and airbills. This file may be accessed through the SMO CLPSS Portal, or can be obtained from the RSCC prior to sampling.

7.2.4 Obtain Shipping Company Information

Samplers should also verify the shipping company information, including the following:

- Company name
- Telephone number
- Account number
- Pickup schedule

Additional guidance will be provided by the U. S. Environmental Protection Agency (EPA) if samples are to be shipped internationally. Also, see Appendix F, International Shipping.

7.2.5 Prepare Sample Container Return Documentation

CLP laboratories must routinely return sample shipping containers to the appropriate sampling office within 14 calendar days following receipt of shipment from the sampler. To ensure that empty sample shipping containers are returned to the appropriate sampling office, samplers must complete the applicable container documentation and work with Regional personnel and government agencies to provide a cost-effective mechanism for this process. The sampling container return documentation should be prepared in advance and provided to samplers before field activities begin.

The sampler (not the CLP laboratory) is responsible for the cost of the return or disposal of the container and should also include shipping airbills bearing the sampler's account number, as well as a return address, to allow for container return.

To maintain consistency across shipping container transportation programs, samplers should proceed as follows:

- Minimize the use of multiple transportation carriers.
- Use multiple-copy labels so the laboratory and the sampling team can each retain a copy for their records.
- Prepare labels in advance so that the laboratory can simply affix a completed shipping label on the container.
- Include third-party billing information (i.e., their shipping account number) on labels so the laboratory will not be billed by the transportation carrier.
- Confirm that the laboratory has been notified of the transportation carrier being used.
- Include the SMO CLPSS Portal-generated CLP Case Number on the return information.

7.3 Collecting Samples

The CLP requirements for sample volumes, preservation, and contractual holding times are defined by the applicable CLP SOWs, and outlined in the tables in Appendix D.

Samplers should follow the sample collection requirements for analyses as provided in the following tables in Appendix D:

- Organic methods (Tables D-1 and D-2)
- Inorganic methods (Table D-3)
- High Resolution methods for Dioxins/Furans and Chlorinated Biphenyl Congeners (CBCs) (Table D-4).

For an explanation of the various sample types and the requirements for collecting and submitting each particular type, refer to Table 7-1.

Table 7-1. Sample Types and CLP Submission Requirements

Sample Type	Purpose	Collection[1]	CLP Sample Number
Field Sample	To analyze for target analytes of interest	Collect from areas that are known or suspected to be contaminated. Collect at the frequency specified in the Quality Assurance Project Plan (QAPP) and Sampling and Analysis Plan (SAP).	Assign CLP Sample Numbers to the sample.
Field Duplicate	To check reproducibility of laboratory and field procedures To indicate non-homogeneity	Collect from areas that are known or suspected to be contaminated. Collect at the frequency specified in the QAPP and SAP.	Assign two separate (unique) CLP Sample Numbers (i.e., one number to the field sample and one to the duplicate). Submit single blind to the laboratory.

Table 7-1. (Continued) Sample Types and CLP Submission Requirements

Sample Type	Purpose	Collection[1]	CLP Sample Number
Field Blank	To check cross-contamination during sample collection, preservation, and shipment, as well as in the laboratory Also to check sample containers and preservatives	Collect for each group of samples of similar matrix at the frequency specified in the QAPP and SAP. Organics - Use water (demonstrated to be free of the contaminants of concern). Inorganics - Use metal-free (deionized or distilled) water or a single clean wipe.	Assign separate CLP Sample Numbers to the field blanks. Submit single blind to the laboratory.
Filter Blank	To check contamination of samples from filtering procedure	Collect when water samples are filtered by filtering blank water using the same procedure and filtering equipment that is used for samples. Use blank water (water demonstrated to be organic-free, deionized or distilled for inorganics) and collect into sample containers.	Assign separate CLP Sample Numbers to the filter blanks. Submit single blind to the laboratory.
Temperature Blank	To provide an accurate measurement of field sample temperature upon arrival to the laboratory Also to establish whether the temperature range has been maintained while in transit	Collect for each shipping container with the frequency specified in the QAPP and SAP.	Ship together with samples from the field to the laboratory. A CLP Sample Number is not required.
Trip Blank [Volatile Organic Analyte (VOA) analysis Only]	To check contamination of VOA samples during handling, storage, and shipment from field to laboratory	Prior to going into the field, prepare and seal one trip blank sample per shipment per matrix. Trip blanks should be matched with respect to matrix and volume of the preservatives used. Prepare trip blank samples with the same preservatives and reagent water used for the corresponding samples. Carry each through the same sampling and handling protocols used for field samples. Aqueous trip blank samples should be prepared using water demonstrated to be free of the contaminants of concern (deionized water is appropriate). Place one trip blank sample for each matrix in each container used to ship VOA samples.	Assign separate CLP Sample Numbers to the trip blanks. Submit single blind to the laboratory.
Equipment Blank or Rinsate Blank	To check field decontamination procedures	Collect when sampling equipment is decontaminated and reused in the field or when a sample collection vessel (bailer or beaker) will be used. Use blank water (water demonstrated to be organic-free, deionized or distilled for inorganics) and pour rinse water into the sample containers.	Assign separate CLP Sample Numbers to the equipment blanks/rinsate. Submit single blind to the laboratory.

Table 7-1. (Continued) Sample Types and CLP Submission Requirements

Sample Type	Purpose	Collection[1]	CLP Sample Number
Matrix Spike (MS) and Matrix Spike Duplicate (MSD) (Organic Analysis Only)	To check accuracy and precision of organic analyses in specific sample matrices	Collect from areas that are known or suspected to be contaminated. MS/MSD are optional per Regional direction.	Assign the same CLP Sample Number to the field sample and the extra volume for MS/MSD. Identify the sample designated for MS/MSD on the TR/COC Record.
Matrix Spike (MS) and Laboratory Duplicate (Inorganic Analysis Only)	To check accuracy and precision of inorganic analyses in specific sample matrices	Collect from areas that are known or suspected to be contaminated. It is recommended that MS and Duplicates be collected in the first round of sampling and included in the first shipment of samples to the laboratory.	Assign the same CLP Sample Number to the field sample and extra volume (if collected). Identify the sample(s) designated for MS and Duplicates on the TR/COC Record.
Performance Evaluation (PE) Samples	Specially-prepared Quality Control (QC) samples used to evaluate a laboratory's analytical proficiency	The PE samples contain analytes with concentrations unknown to the laboratory. Designated Regional or authorized personnel (depending on Regional policy) arrange for Case-specific CLP PE samples to be prepared and shipped by the Quality Assurance Technical Support (QATS) contractor. The PE samples can be shipped to the site, or shipped per Regional direction. QATS provides the appropriate preparation instructions and chain of custody materials.	Samplers must order PE samples and ship them to the laboratory if required by the Region. Assign separate CLP Sample Numbers to the PE samples. Include PE ampule numbers on the TR/COC Record.

[1] Consult Regional or Project Manager Guidance for field QC sample frequencies; laboratory QC sample frequencies are generally fixed in the laboratory contracts or specified in analytical methods.

7.3.1 Field QC Samples

Field QC samples are designed to assess variability of the media being sampled and to detect contamination and sampling errors in the field. The types of field QC samples that are generally collected include the following:

- Field duplicates
- Field blanks (such as equipment, trip, or rinse blanks)

Unless otherwise instructed, field duplicate samples should remain "blind" to the laboratory (i.e., they should have separate CLP Sample Numbers).

7.3.2 Laboratory QC Samples

A laboratory QC sample is an additional analysis of a field sample, as required by the laboratory's contract. There are three types of such samples:

- MS (for organic and inorganic samples)
- MSD (for organic samples only)
- Duplicates (for inorganic samples only)

Samplers should observe the following guidelines when collecting laboratory QC samples:

☐ Follow Regional guidance regarding the collection of laboratory QC samples.

- Regarding Gas Chromatography/Mass Spectrometry (GC/MS) organic analyses, a Region may decide to reference Deuterated Monitoring Compounds (DMCs) rather than MS/MSD for accuracy and precision.

- ☐ Wipe samples do not require laboratory QC samples.
- ☐ When laboratory QC is scheduled for CLP analyses, samplers should select one sample per matrix per Sample Delivery Group (SDG). An SDG closes when 20 samples are received for a Case or one week (3 days for 7-day turnaround samples) has elapsed, whichever comes first. Designate MS/MSD for Pesticides, Aroclors, and GC/MS analyses as directed. For GC/MS, MS/MSD are optional per Regional direction. Designate MS and laboratory Duplicate for metals, mercury, cyanide, anions, hexavalent chromium, and Total Organic Carbon (TOC). Samplers should not select a field blank or a PE Sample for laboratory QC.
- ☐ Designated samples should be identified on the TR/COC Record; the sample(s) designated for laboratory QC should be noted in "Sample Type" column.
- ☐ QC samples should be shipped in the same container as the field samples when possible.

Field QC samples should not be designated as laboratory QC samples.

In the event of multiple sample shipments during a sampling event, it is recommended that the sampler submit laboratory QC samples in the first sample shipment, and as necessary in subsequent shipments to meet laboratory contract requirements.

7.4 Recording Samples

Samplers must use Scribe to record the samples that are collected. To record the samples:

- ☐ Access the Scribe **Sampling** tab to select the type of sampling (Water Sampling, Soil/Sediment Sampling, Wipe Sampling).
- ☐ Enter the detailed information for the sample. Include laboratory analysis for each sample; see tabs for sample details and for analysis.
- ☐ When all information has been entered, click the **Close** button at the bottom of the page to save the entries and close the window.

Refer to Table 5-1 for the CLP analysis codes.

For assistance while using the Scribe software, contact the Environmental Response Team (ERT) Software Support Help Desk at 800-999-6990 from 9:00 AM – 5:00 PM ET. Refer to the following website for information on the use and training of Scribe:
https://response.epa.gov/site/site_profile.aspx?site_id=ScribeGIS

7.4.1 Hardcopy Recording

In the event that Scribe is unavailable, samplers must have backup hardcopy Scribe TR/COC Records. This should be done only in cases of power/equipment failure, and not as a matter of routine during a sampling event.

7.5 Meeting Volume, Preservation, and Holding Time Requirements

Samplers should refer to Tables D-1 through D-4 in Appendix D to obtain the specific sample volumes to be collected, the preservation needed for those samples, and the technical holding times under which they must submit samples to the scheduled CLP laboratory.

7.5.1 Collect Required Sample Volumes

Samplers should ensure that a sufficient volume is collected for each sample. If the sample volume does not meet the requirement set by the project plan, the laboratory may not be able to analyze the sample correctly. Questions regarding collecting lesser volumes than those listed in Tables D-1 through D-4 in Appendix D should be directed to ASB.

Refer to Appendix B for information regarding the collection of aqueous VOA samples. When collecting samples for VOA in soils, samplers must use the SW-846 Method 5035A guidelines included in Appendix C.

If tissue samples are homogenized or processed, it should be performed at a sample processing facility under clean room conditions to reduce potential contamination. Tissue samples should be packed and cooled on ice immediately. Tissue samples should never be sent on Friday for Monday delivery.

7.5.2 Preserve Samples

Without preservation, some samples (e.g., VOAs) may degrade to the point that they will not provide accurate results for the site. The sampler must chemically preserve some water samples for certain analytes prior to shipping them to the laboratory.

Samplers should observe the following procedures:

- ☐ Note any visible reaction between the sample and added chemical preservative in the field record.
- ☐ Preserve and immediately cool all organic, cyanide, hexavalent chromium, and anions (nitrate, nitrite, orthophosphate, and sulfate) water samples to ≤ 6°C, but not frozen, upon collection.
- ☐ Keep samples cooled until shipping (do not freeze water samples).
- ☐ Preservation techniques vary among Regions, so samplers should obtain Region-specific instructions and review the appropriate project plans and Standard Operating Procedures (SOPs).
- ☐ Refer to Appendix B for information regarding the collection of VOA water samples.

7.5.3 Ship Samples within Holding Times

There are two types of holding times: technical and contractual.

- **The technical holding time** is the maximum amount of time allowed between sample collection and the completion of sample extraction and/or analysis.
- **The contractual holding time** is the maximum amount of time that the CLP laboratory can hold a sample prior to extraction and/or analysis. The contractual holding time is the elapsed time expressed in days from the date of receipt of the sample by the laboratory until the date of its extraction and/or analysis, as specified in the applicable CLP SOW.

Contractual holding times are generally set to be two days less than the technical holding times to allow for sample packing and shipping.

Samplers should ship samples to scheduled CLP laboratories as soon as possible after collection.

- Ship samples daily to CLP laboratories whenever possible.
- Samples for certain anions (nitrate, nitrite, and orthophosphate) must ship the same day to meet holding times.
- If samples cannot be shipped on a daily basis, they must be properly preserved and maintained to meet CLP-specified temperatures, holding times, and custody requirements.
- Uploading the electronic TR/COC Record is mandatory and should be performed as soon as possible after shipping.

If samplers are shipping samples after 5:00 PM ET, they should notify the RSCC (or designee) and SMO by 8:00 AM ET on the following business day. When making a Saturday delivery, samplers should notify the RSCC (or designee) and SMO as soon as possible so that SMO will receive the delivery information (including shipping airbill information) by 3:00 PM ET on the Friday prior to delivery. Uploading the electronic TR/COC Record to the SMO CLPSS Portal sends a notification to SMO and to the laboratory that the samples have been shipped.

7.6 Completing the Documentation

The sample documentation required is defined by the project plan. It is highly recommended that samplers provide documentation, even if the Region does not require it.

In general, samplers must complete the following documentation for the samples collected:

- CLP Sample Number (on the sample container or bottle)
- Sample label
- Chain of custody seals (as appropriate)
- TR/COC Record
- Field operations records (as necessary)

Under no circumstances should the site name or address appear on any documentation being sent to the laboratory, unless the laboratory is a Regional EPA laboratory.

An example of a packaged sample is shown in Figure 7-1.

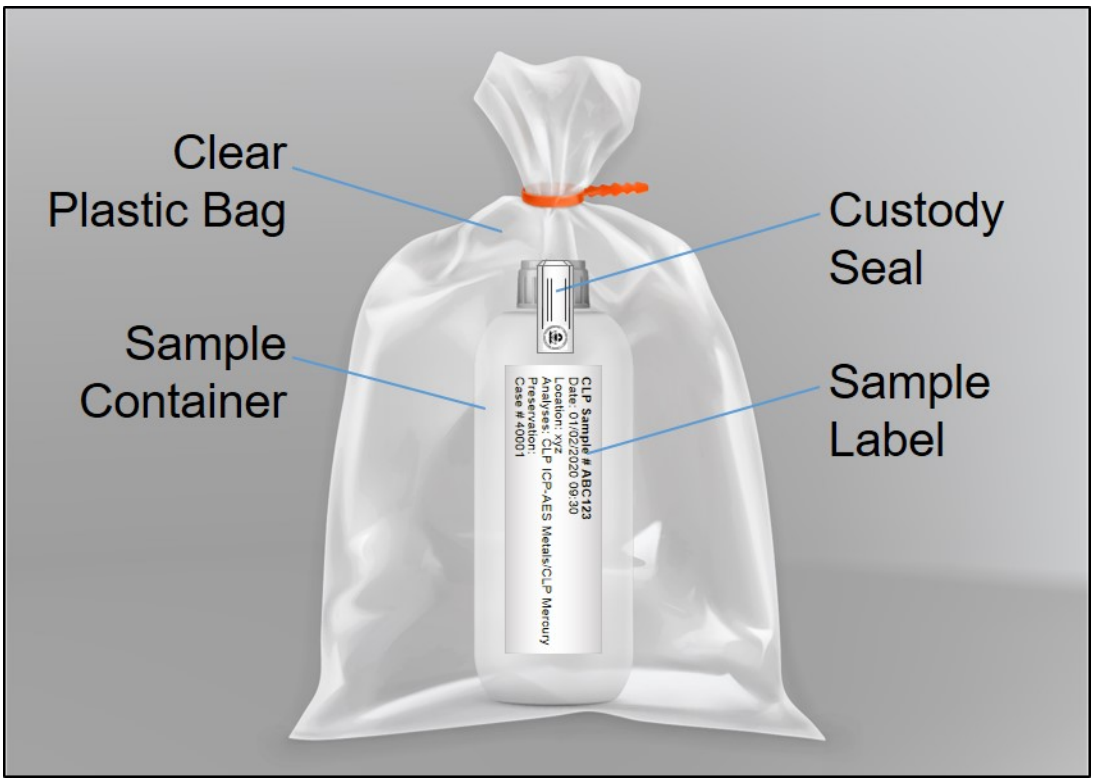

Figure 7-1. Packaged Sample with Identification and Chain of Custody Documentation (Excluding TR/COC Record)

7.6.1 Record and Label the Samples

The sample labels created in Scribe must be affixed to each sample container. A sample label contains the following information:

- Associated CLP Sample Number (either written or pre-printed)
- SMO CLPSS Portal-generated CLP Case Number
- Preservative used
- Analysis
- Additional information such as the location or the date/time of collection

Samplers should record and label the samples collected as follows:

- ☐ Using Scribe, select the **Sampling** tab to select the type of matrix (e.g., Soil/Sediment, Water Sampling).
- ☐ Access the Scribe **Sample Details** page to enter the analysis method, CLP Sample Number, and SMO CLPSS Portal-generated CLP Case Number for each sample.
- ☐ Enter samples associated with an MA by using the MA analysis previously created in Scribe. If the MA does not exist, refer to Section 5.1.2, Create Analysis Types, to create the analysis type for the MA.
- ☐ Print the sample label and place it on the sample container or bottle.
- ☐ If handwriting a sample label, complete the information using waterproof ink, place the label on the outside of the sample bottle or container, then cover the label with clear packaging tape to protect it and maintain legibility.
- ☐ Avoid wrinkles in the tape and labels.
- ☐ Sample tags are NOT required by the CLP.
- ☐ Refer to Figure 7-1 for an example of sample label placement.

Use the following guidelines for these special conditions:

- **Water samples collected for total metals and filtered metals analyses from the same sampling location** - must assign separate (unique) CLP Sample Numbers.
- **Tared VOA sample vials** - must not attach labels to tared VOA sample vials.

7.6.2 Complete the COC Records in Scribe

Samplers should use the Scribe format for CLP projects. Complete the Scribe COC Record as follows:

Access the Scribe COC Page

- Select the **Chain of Custody** link under the **Sample Management** header. The ***Chain of Custody*** page displays.

Create the COC Record

- Click the **Add a Chain of Custody** button at the bottom of the page. The ***COC Details*** pop-up window displays.
- Enter the information for the COC, including selecting the **CLP format** (Inorganic, Organic, or High Resolution).

  Note: It is important that the correct **COC Format** is selected when the COC Record is created. The user should choose the CLP format for the type of samples being submitted, as shown in Figure 7-2.

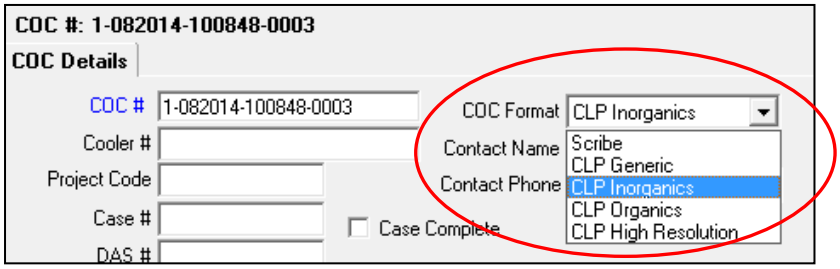

Figure 7-2. COC Details Pop-up Window

- Ensure that the **Case #** is also filled in. (If it was entered in the CLP/Tag Settings, it will automatically be filled in.)

Assign Samples to the COC Record

- Assign samples to the **COC Record** (it will filter based on selected COC format SOW).
- Ensure that all sample information has been entered.
- Enter any additional information, such as sampler name, matrix, and preservation.
- Indicate any samples that will be analyzed using an MA.
- Scribe generates a laboratory and a Regional copy of the COC Record (see Figures 7-3 and 7-4).

Print the COC Record

- Print the **COC Record** by selecting either the **Lab Copy** or **Region Copy**. There will be a QC check; ensure that all information is filled in.
- Print as many copies of the **COC Record** as is necessary.
- Sign and submit original copies of the **COC Record**.

Sampler information, etc., is not added when creating the COC Record; it is added when editing the sample itself.

7.6.3 Making Manual Edits to Printed Scribe COC Records

If a Scribe COC Record has been printed and deletions or edits need to be made, samplers must use the following procedures:

- If making a deletion, delete the incorrect information in Scribe, reprint the COC Record, and discard the original.
- If making an addition, enter the new information in Scribe, reprint the COC Record, and discard the original.
- If corrections occur after shipment, adhere to the Regional procedures and guidelines for handling hardcopy COC Records.

Figure 7-4. Scribe Chain of Custody Record (Region Copy)

7.6.4 Complete and Attach Custody Seals

Custody seals are usually pre-printed stickers that are signed (or initialed) and dated by the samplers after sample collection and placed on sample bottles or containers and/or shipping containers (see Figure 7-5).

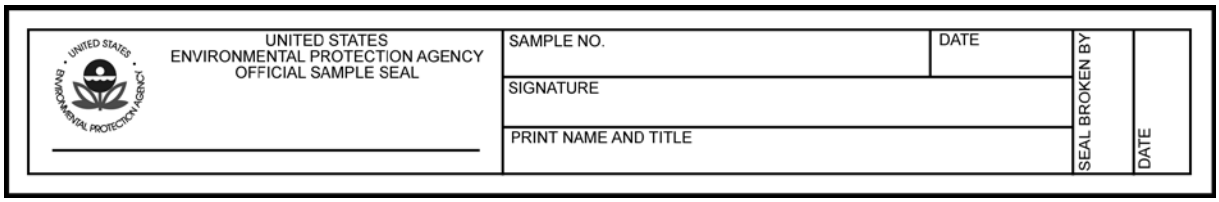

Figure 7-5. Custody Seal

The custody seal documents the individual who sealed the sample container and verifies that the sample has not been tampered with. Custody seals can also be used to maintain custody of other items such as envelopes.

The use and type of custody seals can vary by Region or collecting organization. Samplers should obtain the appropriate custody seals and specific instructions for their use from the RSCC. Note that some Regions require the sampling team to provide their own custody seals.

- Custody seals shall be placed in such a manner that they will break if the sample bottle or container, or the shipping cooler or container is tampered with or opened after leaving custody of the samplers.
- Custody seals should never be placed directly onto a coring tool used as a transport device (e.g., 5 g Sampler) or tared, 40 mL closed-system vials. The seals must be placed on the bag for the coring tool used as a transport device, or on the bag used to enclose the vials. Refer to Table 8-1 for details.

Instructions for completing and attaching a custody seal are included in Table 7-2.

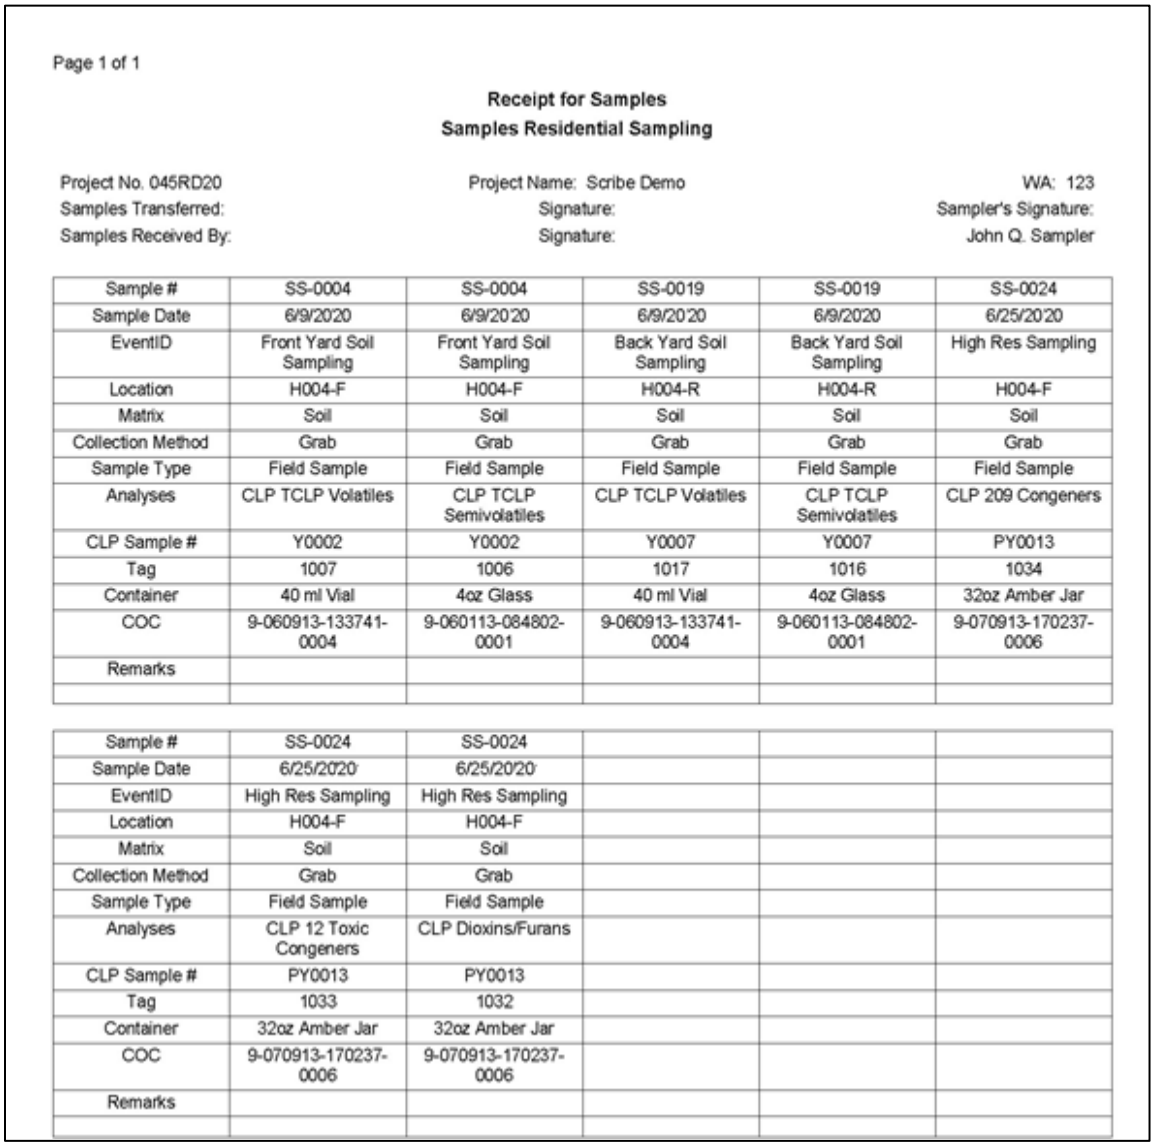

Table 7-2. Completing and Attaching a Custody Seal

Step	Action	Important Notes
1	Record the CLP Sample Number.	The space for the CLP Sample Number does not need to be completed on custody seals being placed on the opening of a shipping container, only on those being placed on the opening of sample bottles or containers.
2	Record the month, day, and year of sample collection.	
3	Sign the seal in the signature field.	
4	Print your name and title in the “Print Name and Title” field.	
5	Place the custody seal over the edge of the sample bottle or container such that it will break if tampered with.	Custody seals can be placed directly on any sample container except for coring tools used as a transport device (e.g., 5 g Samplers) and tared VOA bottles. If packing coring tools used as a transport device or tared VOA bottles, place them in a clear plastic bag and place the custody seal on the outside of the bag.
6	If possible, cover the custody seal with clear plastic tape to protect it.	Take special care to not place the protective tape over the seal in such a way that it can be removed and then re-attached without signs of tampering.

7.7 Providing a Sample Receipt

After samples have been collected on private property, the sampler should prepare a receipt for these samples and provide it to the property owner. This step is especially important when sampling on private property since the analytical results from these samples could be used during future litigation, and the receipt will serve as proof that the owner granted approval for the removal of the samples from the property. An example of a sample receipt created using Scribe is shown in Figure 7-6.

Detailed instructions for generating a Sample Receipt Report are included in Exercise 9 - Section K of the "V 3.10.1 Scribe Training Guide.PDF" which can be obtained from this download: https://response.epa.gov/sites/ScribeGIS/files/Scribe%20V310%20Student%20Files.zip

8.0 CLP SAMPLE TRANSPORTATION AND SHIPPING

The sampling organization is not only responsible for the transportation and shipping of the Contract Laboratory (CLP) samples to the scheduled recipient laboratory that will be performing the analysis, but it is also responsible for complying with all applicable packaging, labeling, and shipping requirements. Samplers should review the applicable project plans to be aware of all State, Federal, Department of Transportation (DOT), and International Air Transport Association (IATA) regulations governing environmental and hazardous sample packaging.

8.1 Providing Shipment Notification

Some Regions may require that samplers notify their Regional Sample Control Coordinator (RSCC) (or designee) when samples are shipped, while other Regions may allow samplers to contact the Sample Management Office (SMO) directly to provide shipping notification. It is recommended that the electronic Chain of Custody (COC) Record be submitted through the Contract Laboratory Program Support System (CLPSS) (aka "the SMO CLPSS Portal") as soon as possible after shipping. Submitting the COC Record electronically sends a notification to SMO and to the laboratory that the samples have been shipped. It is recommended that samplers contact the RSCC to verify if such notification is necessary. If samplers are shipping samples after 5:00 PM ET, they should notify the RSCC (or designee) and SMO by 8:00 AM ET on the following business day.

It is strongly recommended that samplers provide shipping notification to the RSCC even if they have received approval to directly notify SMO so that the Region is aware of any changes in the final number and timing of samples delivered.

8.2 Packing and Shipping Samples

After collecting the samples, it is important that the samplers properly package them for shipment and ensure that the samples are sent to the appropriate laboratory without delay. Prompt and proper packaging of samples will achieve the following:

- Protect the integrity of samples from changes in composition or concentration caused by bacterial growth or degradation from increased temperatures.
- Reduce the chance of leaking or breaking of sample containers that would result in loss of sample volume, loss of sample integrity, and exposure of personnel to toxic substances.
- Help ensure compliance with shipping regulations.

A single CLP sample may be contained in several different bottles and vials. For example, one water sample may consist of all containers needed for three of the analytical analyses available under this service [i.e., Semivolatile Organic Analyte (SVOA) analysis, Pesticide analysis, and Aroclor analysis], even though the analyses are collected in separate containers. Therefore, the analysis to be performed and the matrix type will determine the type of container(s) that will be used, as well as the volume that should be collected for that particular sample analysis.

8.2.1 Inventory of Samples and Documentation

Samplers should inventory the contents of shipping containers against the corresponding Traffic Report/Chain of Custody (TR/COC) Records when packing samples for shipment to laboratories. Check for the following:

- Ensure that the correct number of containers has been collected for each analysis of the samples.
- Confirm that the required Performance Evaluation (PE) and Quality Control (QC) samples and temperature blanks are included in the shipment.
- Verify that the correct sample numbers and analyses have been assigned to each sample.

8.2.2 Shipping Regulations

Sample shipping personnel are legally responsible for ensuring that sample shipments comply with all applicable shipping regulations. Verify that the following shipping regulations are adhered to if any of the following conditions apply to the samples:

Note: Field Samplers are legally required to know sample characteristics before shipping.

- **Foreign soil movement** - Follow U.S. Department of Agriculture (USDA) soil quarantine and shipping requirements, providing soil permits or required soil import agreements to the laboratory for completion.
- **Chlorinated Dibenzo-*p*-Dioxin (CDD) and Chlorinated Dibenzofuran (CDF)** - Refer to the High Resolution Superfund Method Statement of Work (SOW) for specific information on the safety and handling requirements for samples potentially containing CDD/CDF.
- **Radiological** - Samples suspected to be radioactive must be screened; follow the instructions from the Analytical Services Branch (ASB) Program Manager. Radioactive/Radiological samples are NOT accepted by the CLP.
- **Dry ice** - If dry ice is used to ship tissue samples, follow DOT and IATA regulations. Refer to the Code of Federal Regulations (49 CFR 173.217) classifying dry ice as Hazard Class 9 *UN 1845* (Hazardous Material) and IATA Dangerous Goods regulations or DOT regulations and U.S. Environmental Protection Agency (EPA) guidelines. Refer to Appendix C for detailed shipping guidelines when using SW-846 Method 5035A to preserve and ship frozen samples.

When shipping from remote locations, dry ice may be used with water ice for the purpose of keeping the water ice from melting. Wrap the dry ice in newspaper and place above any water ice. Never place dry ice in an air-tight container.

Access more transportation and shipping information using the following websites:

Dangerous goods regulations
IATA website
https://www.iata.org/en/programs/cargo

DOT/Pipeline and Hazardous Materials Safety Administration (PHMSA)
https://www.phmsa.dot.gov/phmsa-regulations

The nature of the samples collected determines the type of shipping materials to be used.

Refer to the project plan to determine which type of shipping container should be used for each type of sample collected during the sampling event.

8.2.3 Shipping Temperature

Samples must be stored under conditions that maintain sample integrity.

- Samples requiring cold preservation should be placed in shipping containers or other suitable containers with ice to reduce the temperature as soon as possible after collection.
- Ideally, all samples should be shipped the day of collection for overnight delivery to the laboratory.
- If samples requiring cold preservation cannot be shipped on the day of collection, the sample temperature should be maintained at ≤ 6°C, but not frozen, until they are shipped to the laboratory.

8.2.4 Pack Shipping Containers

Packing shipping containers correctly will prevent sample containers from breaking and leaking. Pack shipping containers according to the instructions outlined in Table 8-1.

Table 8-1. Packing Samples for Shipment

Step	Action	Important Notes
1	Seal all drain holes in the shipping container, both inside and out, to prevent leakage in the event of sample breakage.	
2	Check all lids/caps to make sure the samples are tightly sealed and will not leak.	
3	Wipe loose soil residue from containers.	
4	Seal samples in a clear plastic bag.	Custody seals can be placed directly on any sample container except for coring tools used as a transport device (e.g., 5 g Samplers) and tared Volatile Organic Analyte (VOA) bottles. If packing coring tools used as a transport device or tared VOA bottles, place them in a clear plastic bag and affix the custody seal to the outside of the bag.
5	Fully chill those samples that require chilling to ≤ 6°C (but not frozen) prior to placing in the container with suitable packing materials.	
6	It is recommended that samplers line shipping containers with non-combustible, absorbent packing material prior to placing samples in the shipping container.	The CLP strongly discourages the use of vermiculite and cat litter as sources for packing material. These materials interfere with labeling and documentation and are difficult to remove from sample containers and shipping containers.
7	Place samples in CLEAN, sealed, watertight shipping containers (e.g., metal or hard plastic coolers).	
8	Conduct an inventory of the contents of the shipping cooler/container against the corresponding TR/COC Record(s).	
9	Cover samples in double-bagged ice to prevent water damage to packing materials.	Do NOT pour loose ice directly into the sample container. The ice is used to maintain the temperature of the samples in the shipping cooler.
10	It is recommended that a temperature blank be included each shipping container in a location which will allow for easy access by the laboratory upon opening the shipping container.	The temperature blank is generally a 40 mL vial filled with water and labeled “temperature blank” but does not have a CLP Sample Number.
11	Ensure that the site name or other site-identifying information does not appear on any documentation being sent to the laboratory.	

Table 8-1. (Continued) Packing Samples for Shipment

Step	Action	Important Notes
12	Label the outside of the shipping container with any instructions for handling, such as, “This end up,” “Do not Tamper With,” or "Environmental Laboratory Samples."	
13	If shipping samples containing methanol as a preservative (e.g., samples to be analyzed by SW-846 Method 5035A), use a label to indicate the presence of methanol, the United Nations (UN) identification number for methanol (UN 1230), and Limited Quantity.	

VOA soil samples must be placed on their side prior to being placed on ice. Vials are placed on their side so that the septum is wet on the inside, thereby preventing vapor leaks around it, in case any bubbles form. Also, in case the samples freeze, the water will expand into the flexible septum rather than breaking the vial.

8.2.5 Include Required Paperwork

☐ Attach the necessary paperwork to the shipping cooler or container. All paperwork must be placed in a plastic bag or pouch and then secured to the underside of the shipping container lid (Figure 8-1).

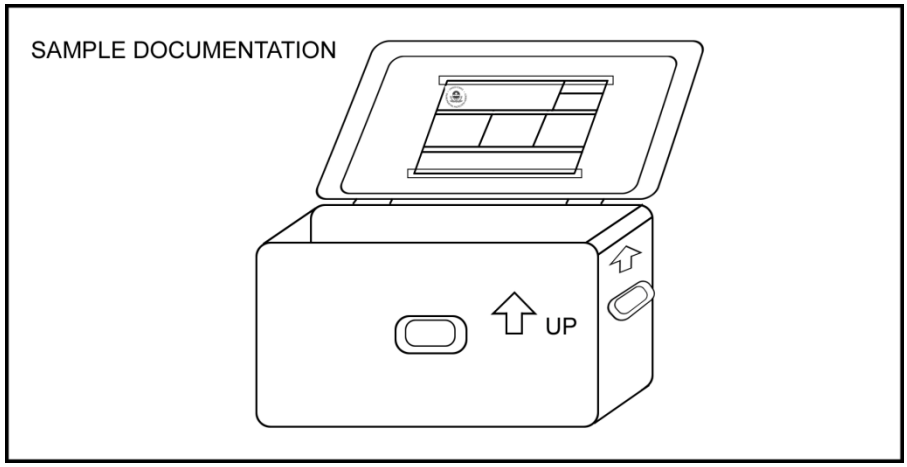

Figure 8-1. Sample Shipping Container with Attached TR/COC Record, PE Sample Instructions (if applicable), and Container Return Documentation

Required paperwork includes:

- TR/COC Records
- Sample weight logs (Figure 4-1), if required for VOA samples
- PE instruction sheets if PE samples are included in the container
- Shipping container return instructions and/or airbills

Contact the RSCC (or designee) for specific paperwork requirements.

8.2.6 Label and Seal Sample Shipping Containers

After packing the samples in the shipping containers, samplers must carefully secure the top and bottom of the containers with tape, place return address labels clearly on the outside of the container, and attach the required chain of custody seals (Figure 8-2).

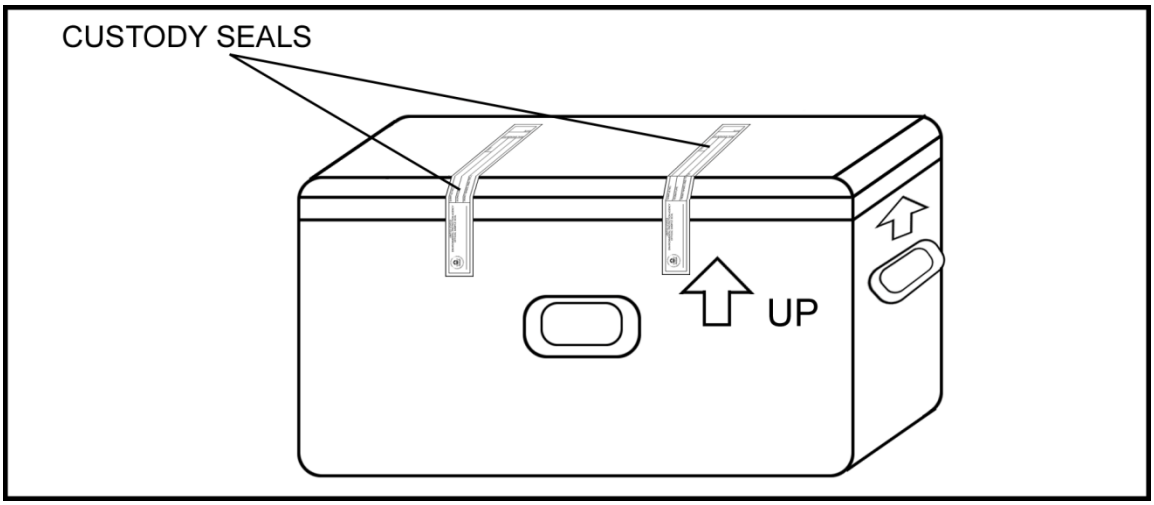

Figure 8-2. Shipping Container with Custody Seals

Use the following guidelines to label shipping containers:

- When shipping more than one container to a laboratory, samplers should mark each container as "1 of 2," "2 of 2," etc.
- An airbill, addressed to the Sample Custodian of the receiving laboratory, must be completed for each container shipped. Samplers should receive the correct name, address, and telephone number of the laboratory to which they must ship samples from the RSCC or the SMO CLPSS Portal.
- To avoid delays in analytical testing, it is critical that for samples associated with multiple types of analyses the correct containers with the correct types of samples are sent to the correct laboratory. For example, inorganic samples may be shipped to one laboratory for analysis, while organic samples may need to be shipped to another laboratory.
- Confirm the shipping company's hours of operation, shipping schedule, and pick-up/drop-off requirements.

8.2.7 Overnight Delivery

It is imperative that samples be sent via overnight delivery. Delays due to longer shipment times may result in missed technical holding times or temperatures rising above the preservation limit, which may destroy sample integrity or require the re-collection of samples for analysis.

8.2.8 Saturday Delivery

Samplers should notify the RSCC (or designee) and SMO as soon as possible when shipping samples for Saturday delivery, so that the delivery information is received by 3:00 PM ET on the Friday prior to delivery.

8.2.9 Shipment Notification

Samplers should upload shipment information to the SMO CLPSS Portal and report all sample shipments to the RSCC (or designee) on the day shipping is completed. **Under no circumstances**

should the sampler contact the laboratory directly. If samplers are shipping samples after 5:00 PM ET, they should notify the RSCC (or designee) or SMO by 8:00 AM ET on the following business day. Samplers should receive the name, phone number, and email address of the appropriate SMO coordinator to notify from the Region/RSCC. Samplers should be aware if the Region requires them to notify the RSCC (or designee) and SMO of sample shipment.

Samplers should provide the following information to the RSCC (or designee):

- Name, phone number, and email address at which they can be reached (preferably closest on-site phone number if still in the field)
- SMO CLPSS Portal-generated Case Number
- Number, matrix and analysis types of samples shipped, and MA number (if required)
- Name of laboratory (or laboratories) to which the samples were shipped
- Airbill number(s)
- Date of shipment
- Case status (i.e., whether or not the Case is complete)
- Problems encountered, special comments, or any unanticipated issues
- Information for the next anticipated shipment

For Saturday delivery, samplers should notify the RSCC (or designee) and SMO as soon as possible so that SMO will receive the delivery information (including shipping airbill information) by 3:00 PM ET on the Friday prior to delivery. Uploading the electronic COC to the SMO CLPSS Portal sends a notification to SMO and to the laboratory that the samples have been shipped.

8.2.10 Uploading the Electronic COC

The electronic COC Record must be uploaded to the SMO CLPSS Portal as soon as possible after sample shipment. The following is an overview of the steps used to upload the electronic COC Record:

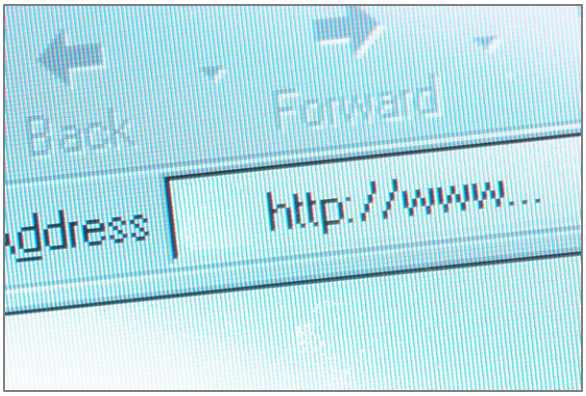
☐ Using **Scribe**:

- Under **Sample Management**, click on the **Chain of Custody** link.
- Click the **Export** button on the top of the menu bar.
- Select the **COC XML File (.xml)** option.
- Select the **COC(s)** to be exported.
- Make sure that the **CLP Region Copy COC XML Template** is checked.
- Click **OK**.
- Provide a **filename** for the exported XML file. Per CLP guidance, the XML file name must reference the Region #, Case Number, and the date.
- Click the **Save** button.

☐ Using the SMO **CLPSS Portal**:

- Select the **Submit Chain of Custody** task.
- **Select** the COC file to upload.
- Enter any **comments** associated with the COC file.
- **Submit** the file; CLPSS provides a confirmation page.
- **Print or download** a copy of the submission summary to keep as a record of the submission.

For a detailed description of how to create and upload electronic COC Record files using Scribe and the SMO CLPSS Portal, refer to each system's user documentation.



8.2.11 Return of Sample Shipping Containers

CLP laboratories must routinely return sample shipping containers within 14 calendar days following shipment receipt. Therefore, the sampler should also include container return instructions with each shipment. Note that the **samplers** (not the CLP laboratory) are responsible for the costs of return or disposal of these containers and should include shipping airbills bearing the sampler's account number, as well as a return address. **Samplers should use the least expensive return shipping option possible.**

This page is intentionally left blank.

9.0 SAMPLER RESOURCES

This Guidance document provides a summary of the many resources used to define and manage the sampling process. Samplers may need to refer to the original source documents or websites for further information or clarification. The resources cited herein are listed in this section.

9.1 List of Resources

Table 9-1 provides a list of the resources available to samplers and referenced throughout this Guidance document.

APPENDIX A FUNCTIONS WITHIN A SAMPLING PROJECT

The following table describes Quality Assurance Project Plan (QAPP) sampling requirements based on *EPA Requirements for Quality Assurance Project Plans* (EPA QA/R-5).

Table A-1. QAPP Requirements

Functions Within a Sampling Project	Elements of that Function
Project Management	
Project/Task Organization	Identifies the individuals or organizations participating in the project and defines their specific roles and responsibilities.
Problem Definition/Background	States the specific problem to be solved or decision to be made and includes sufficient background information to provide a historical and scientific perspective for each particular project.
Project/Task Description	Describes the activities to be performed and the schedule for implementation to include: • Measurements to be made during the course of the project. • Applicable technical, regulatory, or program-specific quality standards, criteria, or objectives. • Any special personnel and equipment requirements; assessment tools needed. • A work schedule and any required project and quality records, including types of reports needed.
Quality Objectives and Criteria	Describes the project quality objectives and measurement performance criteria.
Special Training/Certification	Ensures that any specialized training required for modified field sampling techniques, field analyses, laboratory analyses, or data validation should be specified.
Documents and Records	• Itemizes the information and records that must be included in the data report package and specifies the desired reporting format for hardcopy and electronic forms, when used. • Identifies any other records and/or documents applicable to the project such as audit reports, interim progress reports, and final reports that will be produced. • Specifies or references all applicable requirements for the final disposition of records and documents, including location and length of retention period.
Data Generation and Acquisition	
Sampling Process Design (Experimental Design)	• Describes the experimental design or data collection design for the project. • Classifies all measurements as critical or non-critical.
Sampling Methods	• Describes the procedures for collecting samples and identifies sampling methods and equipment. Includes any implementation requirements, support facilities, sample preservation requirements, and materials needed. • Describes the process for preparing and decontaminating sampling equipment to include the disposal of decontamination by-products, selection and preparation of sample containers, sample volumes, preservation methods, and maximum holding times for sampling, preparation, and/or analysis. • Describes specific performance requirements for the method. • Addresses the actions to be taken when a failure in sampling occurs, which party is responsible for corrective action, and how the effectiveness of the corrective action shall be determined and documented.

Table A-1. (Continued) QAPP Requirements

Functions Within a Sampling Project	Elements of that Function
Sample Handling and Custody	• Describes the requirements and provisions for sample handling and custody in the field, transport, and laboratory, taking into account the nature of the samples, the maximum allowable sample holding times before extraction and analysis, and the available shipping options and schedules. • Includes examples of sample labels, custody forms, and sample custody logs.
Analytical Methods	• Identifies the analytical methods and equipment required, including sub-sampling or extraction methods, waste disposal requirements (if any), and specific method performance requirements. • Identifies analytical methods by number, date, and regulatory citation (as appropriate). If a method allows the user to select from various options, the method citations should state exactly which options are being selected. • Addresses the actions to be taken when a failure in the analytical system occurs, who is responsible for corrective action, and how the effectiveness of the corrective action shall be determined and documented. • Specifies the laboratory turnaround time needed, if important to the project schedule. • Specifies whether a field sampling and/or laboratory analysis Case Narrative is required to provide a complete description of any difficulties encountered during sampling or analysis.
Quality Control (QC)	• Identifies required measurement QC checks for both the field and laboratory. • States the frequency of analysis for each type of QC check, and the spike analyte sources and levels. • States or references the required control limits for each QC check and the corrective action(s) required when control limits are exceeded and how the effectiveness of the corrective action shall be determined and documented. • Describes or references the procedures to be used to calculate each of the QC statistics.
Instrument/Equipment Testing, Inspection, and Maintenance	• Describes how inspections and acceptance testing of environmental sampling and measurement systems and their components will be performed and documented. Identifies and discusses the procedure by which final acceptance will be performed by independent personnel. • Describes how deficiencies are to be resolved and when re-inspection will be performed. • Describes or references how periodic preventative and corrective maintenance of measurement or test equipment shall be performed. • Identifies the equipment and/or system requiring periodic maintenance. • Discusses how the availability of spare parts identified in the operating guidance and/or design specifications of the systems will be assured and maintained.
Instrument/Equipment Calibration and Frequency	• Identifies all tools, gauges, instruments, and other sampling, measuring, and test equipment used for data collection activities affecting quality that must be controlled, and at specific times, calibrated to maintain performance within specified limits. • Identifies the certified equipment and/or standards used for calibration. • Describes or references the calibration procedures to be conducted using certified equipment and/or standards with known valid relationships to nationally recognized performance standards. If no such standards exist, documents the basis for calibration. • Indicates how records of calibration shall be maintained and traced to the instrument.
Inspection/Acceptance of Supplies and Consumables	• Describes how and by whom supplies and consumables shall be inspected and accepted for use in the project. • States acceptance criteria for such supplies and consumables.

Table A-1. (Continued) QAPP Requirements

Functions Within a Sampling Project	Elements of that Function
Non-direct Measurements	• Identifies all the types of data needed for project implementation or decision-making that are obtained from non-measurement sources (e.g., computer databases, programs, literature files, historical databases). • Describes the intended use of data. • Defines the acceptance criteria for the use of such data in the project. • Specifies any limitations on the use of the data.
Data Management	• Describes the project data management scheme, tracing the data path from generation in the field or laboratory to their final use or storage. • Describes or references the standard record-keeping procedures, document control system, and the approach used for data storage and retrieval on electronic media.

This page is intentionally left blank.

APPENDIX B GENERAL CLP SAMPLE COLLECTION GUIDELINES FOR AQUEOUS VOA SAMPLES

Regional guidance and/or specific Project Plan requirements will supersede the guidelines listed below.

Collect the following:

- At least four 40 mL glass containers with polytetrafluoroethylene (PTFE)-lined septa and open top screw-caps that are filled to capacity with no air bubbles, preserved to a pH of 2 with HCl, and cooled to ≤ 6°C, but not frozen, immediately after collection. DO NOT FREEZE THE SAMPLES.

Regular Samples	4 vials (40 mL filled to capacity with no headspace or air bubbles)
Regular Samples Requiring Quality Control (QC) Analysis	4 vials for Sample (40 mL filled to capacity with no headspace or air bubbles) 2 vials for Matrix Spike (MS) (40 mL filled to capacity with no headspace or air bubbles) 2 vials for Matrix Spike Duplicate (MSD) (40 mL filled to capacity with no headspace or air bubbles)

- If Selected Ion Monitoring (SIM) analysis is requested, at least two additional 40 mL glass containers with PTFE-lined septa and open top screw-caps that are filled to capacity with no air bubbles, preserved to a pH of 2 with HCl, and cooled to ≤ 6°C, but not frozen, immediately after collection.

Regular Samples With SIM Analysis	4 vials for Sample (40 mL filled to capacity with no headspace or air bubbles) 2 vials (40 mL filled to capacity with no headspace or air bubbles)

Test for Carbonates, Residual Chlorine, Oxidants, and Sulfides:

- It is important that samplers obtain Regional guidance when testing and ameliorating for:
  - Carbonates;
  - Residual chlorine (e.g., municipal waters or industrial waste waters that are treated with chlorine prior to use or discharge); or
  - Oxidants.
- Volatile Organic Analyte (VOA) samples containing carbonates react with the acid preservative causing effervescence (due to formation of carbon dioxide), which can cause loss of volatile analytes.
- Residual chlorine present in VOA samples can continue to react with dissolved organic matter. This continuous reaction may lead to inaccurate quantitation of certain analytes present in the sample at the time of collection.
- Residual chlorine and oxidants present in VOA samples can cause degradation of certain volatile analytes (e.g., styrene).

Perform the following for *Pre-Preserved* Vials:

1. Pour the sample slowly down the edge of the sample vial to avoid excess aeration or agitation of the sample during filling.
2. Fill the vial completely so that a reverse (convex) meniscus is present and ensure that there are no air bubbles present (either in the body or especially at the top of the vial).
3. Place the septum on the vial so that the PTFE side is in contact with the sample, and then firmly tighten the cap.

4. Gently flip the vial a few times to ensure that the sample is mixed with the acid preservative.
5. While holding the vial inverted, gently tap the sample to check for air bubbles (either in the body or especially at the top of the inverted vial).
6. If air bubbles are present, discard the sample and select a new vial in which to collect a new sample. Repeat Steps 1 - 5 above.
7. Do NOT mix or composite samples for VOAs.
8. Cool sample to a temperature of ≤ 6°C, but not frozen. Samplers should begin the cooling process in the field as samples are being collected. Double-bagged ice should be used. DO NOT FREEZE WATER SAMPLES.
9. Immediately transfer the vial to the sample shuttle (device that contains a "set" of VOA vials) once it has been collected. Do NOT allow ice to touch the vials.

Perform the Following for *Empty* Vials:

1. Rinse the vial with sample water prior to actual sample collection and preservation.

Regions vary in their approach to pre-rinsing and/or re-using sample vials (e.g., some Regions do not recommend pre-rinsing and/or re-use of pre-cleaned containers using sample water). Be sure to follow Regional guidance.

2. Add 1-2 mL of acid preservative to the vial. Check to ensure that the sample requires a preservative (follow Regional guidance).
3. Pour the sample slowly down the edge of the sample vial to avoid excess aeration and agitation of the sample.
4. Fill the vial completely so that a reverse (convex) meniscus is present and ensure that there are no air bubbles present (either in the body or especially at the top of the vial).
5. Place the septum on the vial so that the PTFE side is in contact with the sample, and then firmly tighten the cap.
6. Gently flip the vial a few times to ensure that the sample is mixed with the acid preservative.
7. While holding the vial inverted, gently tap the vial to check for air bubbles (either in the body or especially at the top of the vial).
8. If an air bubble is present that is larger than ~6 mm (pea size), discard the sample and collect a new sample using the same sample vial. Repeat Steps 1 - 7 above.
9. Check the re-collected sample for air bubbles. If there are air bubbles after three consecutive attempts to eliminate air bubbles by the addition of sample water, the entire sample and sample vial should be discarded and a new sample collected without preservative. Note the absence of preservative due to the impact on holding time.
10. Do NOT mix or composite samples for VOAs.
11. Cool sample to a temperature of ≤ 6°C, but not frozen. Samplers should begin the cooling process in the field as samples are being collected. Double-bagged ice should be used. DO NOT FREEZE WATER SAMPLES.
12. Immediately transfer the vial to the sample shuttle (device which contains a "set" of VOA vials) once it has been collected. Do NOT allow ice to touch the vials.

Things to Remember:

- Samples should be shipped as soon as possible, preferably on the same day as sample collection to avoid exceeding sample holding times. If overnight transit is not possible, samples should be maintained at ≤ 6°C, but not frozen, until they are shipped to the laboratory.
- If samples are not preserved (a requirement for certain analyses), the technical holding time is shortened to 7 days.

This page is intentionally left blank.

APPENDIX C CLP SAMPLE COLLECTION GUIDELINES FOR SOIL VOA SAMPLES BY SW-846 METHOD 5035A, TCLP EXTRACTION BY EPA METHOD SW-846 METHOD 1311, AND SPLP EXTRACTION BY EPA SW-846 METHOD 1312

A. Preferred Options for the Contract Laboratory Program (CLP) are Options 1, 2, 3, and 4:

This analytical method employs sample vials that are filled and weighed in the field and never opened during the analytical process. For this reason, sampling personnel should be equipped with a portable balance capable of weighing to 0.01g.

Soil samples must be placed on their side prior to being frozen or placed on ice. Vials are placed on their side so that the septum is wet on the inside, thereby preventing vapor leaks around it, in case any bubbles form. Also, in case the samples freeze, the water will expand into the flexible septum rather than breaking the vial. Dry ice or field freezers are the only options.

Option 1.

Closed-system Vials:

Container - tared or preweighed 40 mL Volatile Organic Analyte (VOA) Analysis vial containing a magnetic stir bar.

Collect 5 g of soil per vial (iced or frozen in the field). Check the pre-tared weight of the (dry) Volatile Organic Analyte (VOA) vials prior to departure for the sampling event under controlled conditions. Weigh vials and soil samples to the nearest 0.01 g. This check is to ensure that the original weight was properly recorded.

Regular Samples	3 Vials - Dry (5 g soil per vial) 1 Vial - Dry (filled with soil, no headspace) 4 Total Vials
Regular Samples Requiring Quality Control (QC) Analysis	11 Vials - Dry (5 g soil per vial) 1 Vial - Dry (filled with soil, no headspace) 12 Total Vials

Option 2.

Closed-system Vials Containing Water:

Container - tared or pre-weighed 40 mL VOA vial containing a magnetic stir bar and 5 mL water.

Collect 5 g of soil per vial (iced or frozen in the field). Weigh vials and soil samples to the nearest 0.01 g.

Regular Samples	3 Vials with water added (5 g soil and 5 mL water per vial) 1 Vial - Dry (filled with soil, no headspace) 4 Total Vials (3 with water and 1 dry)
Regular Samples Requiring QC Analysis	11 Vials with water added (5 g soil and 5 mL water per vial) 1 Vial - Dry (filled with soil, no headspace) 12 Total Vials (11 with water and 1 dry)

Option 3.

Container - 5 g Samplers or equivalent and coring tool used as a transport device.

All samples should be iced or frozen in the field and bagged individually.

Regular Samples	3 Samplers (5 g soil per Sampler) 1 Vial - Dry (filled with soil, no headspace) 4 Total (3 Samplers and 1 Vial)
Regular Samples Requiring QC Analysis	11 Samplers (5 g soil per Sampler) 1 Vial - Dry (filled with soil, no headspace) 12 Total (11 Samplers and 1 Vial)

Option 4.

Closed-system Vials:

Container - tared or preweighed 40 mL VOA vial.

Collect 25 g of soil per vial (iced or frozen in the field). Check the pre-tared weight of the (dry) VOA vials prior to departure for the sampling event under controlled conditions. Weigh vials and soil samples to the nearest 0.01 g. This check is to ensure that the original weight was properly recorded.

Regular Samples	6 Vials - Dry (25 g soil per vial)

B. Options 5, 6, and 7 are NOT preferred options for the CLP:

Option 5.

Closed-system Vials:

Container - tared or preweighed 40 mL VOA vial containing a magnetic stir bar and preservative.

Collect 5 g of soil per vial and add Sodium bisulfate ($NaHSO_4$) preservative (5 mL water + 1 g $NaHSO_4$) - iced in the field.

Caution: **This option is NOT a Preferred Option for the CLP because:**

$NaHSO_4$ preservation creates low pH conditions that will cause the destruction of certain CLP target analytes (e.g., vinyl chloride, trichloroethene, trichlorofluoromethane, cis- and trans-1,3-dichloropropene). Projects requiring the quantitation of these analytes should consider alternative sample preservation methods. $NaHSO_4$ also cannot be used on carbonaceous soils. Check the soil before using this method of collection! Soils can be checked by placing a test sample in a clean vial, then adding several drops of $NaHSO_4$ solution. If the soil bubbles, use Option 5b and note this issue on the Traffic Report/Chain of Custody (TR/COC) Record.

Option 5a. Samples preserved in the field

Regular Samples	3 Vials with $NaHSO_4$ preservative added (5 g soil per vial) 1 Vial - Dry (filled with soil, no headspace) 4 Total Vials (3 with $NaHSO_4$ preservative and 1 without)
Regular Samples Requiring QC Analyses	6 Vials with $NaHSO_4$ preservative added (5 g soil per vial) 2 Vials - Dry (filled with soil, no headspace) 8 Total Vials (6 with $NaHSO_4$ and 2 without)

Option 5b. Samples to be preserved by the laboratory (No $NaHSO_4$ preservative is added to these samples in the field).

Regular Samples	3 Vials - Dry (5 g soil per vial) 1 Vial - Dry (filled with soil, no headspace) 4 Total Vials
Regular Samples Requiring QC Analyses	6 Vials - Dry (5 g soil per vial) 2 Vials - Dry (filled with soil, no headspace) 8 Total Vials

Option 6.

Methanol Preservation (medium-level analysis only):

Container - tared or pre-weighed 40 mL VOA vials containing 5 mL methanol.

Collect 5 g of soil per vial (iced in the field).

Caution: **This is NOT a preferred option for the CLP because:**

Samples preserved with methanol can only be analyzed by the medium-level method. Low-level Contract Required Quantitation Limits (CRQLs) cannot be achieved when samples are preserved in this manner. If this soil option is used, then samples for low-level analysis by one of the other options should also be collected and accompany the medium-level soil.

Additional problems associated with use of methanol as a preservative in the field include:

- Possible contamination of the methanol by sampling-related activities (e.g., absorption of diesel fumes from sampling equipment);
- Leakage of methanol from the sample vials during shipping, resulting in loss of VOAs prior to analysis.

Regular Samples	2 Vials (5 g soil and 5 mL methanol per vial) 1 Vial - Dry (filled with soil, no headspace) 3 Total Vials (2 with methanol and 1 dry)
Regular Samples Requiring QC Analyses	6 Vials (5 g soil and 5 mL methanol per vial) 1 Vial -Dry (filled with soil, no headspace) 7 Total Vials (6 with methanol and 1 dry)

If shipping samples that contain methanol as a preservative, a shipping label must be used to indicate the presence of methanol. This label must also contain the United Nations (UN) identification number for methanol (UN 1230), and indicate Limited Quantity. Refer to http://www.phmsa.dot.gov for additional information about the safe shipping of methanol.

Option 7.

Glass Containers filled with sample - No Headspace:

Container - 4 oz. Glass Jars.

Glass container filled with soil with no headspace and iced.

Caution: This is NOT a preferred option for the CLP because:

Samples collected in this manner lose most of their volatile analytes prior to analysis when the sample containers are opened and sub-sampled in the laboratory. This option is only available when required by the Region.

Regular Samples	2 Glass Jars (4 oz.) filled with sample, no headspace 1 Vial - Dry (filled with soil, no headspace) 3 Total Containers
Regular Samples Requiring QC Analyses	2 Glass Jars (4 oz.) filled with sample, no headspace 1 Vial - Dry (filled with soil, no headspace) 3 Total Containers

C. Caution:

1. Extreme care should be taken to ensure that frozen or iced samples do not break during shipment.
2. Before adding soil to pre-weighed vials containing a stir bar, weigh the vials to confirm the tared weight. If the weight varies by more than 0.1 g, record the new weight on the label and the sample documentation. Do NOT add labels to these vials once the tared weight has been determined or confirmed.

D. Dry Samples:

Collect in a dry 40 mL VOA vial (or a 4 oz. wide mouth jar) with no headspace. No water, $NaHSO_4$, or methanol is added to this sample. This sample is collected to determine moisture content; therefore, it does not need to be tared or have a stir bar.

E. Iced or Frozen Samples:

1. Iced means cooled to $\leq 6°C$, but not frozen, immediately after collection.
2. Frozen means cooled to $< -7°C$ immediately after collection.
3. Dry ice is not a long-term freezing agent and may contaminate samples.

F. Sample Delivery:

The CLP strongly recommends that all samples arrive at the laboratory by close of business the next day following sample collection.

G. Notes:

1. For Options 2, 5, and 6, check the weight of the pre-tared VOA vials plus liquid in the field due to the possibility that liquid may have leaked out during packing, transit, or deployment in the field just prior to sampling. This check is to ensure that the original weight is properly recorded.
2. For Option 5, samples can be preserved with $NaHSO_4$ either:
   - In the field; or
   - The samplers must evaluate whether $NaHSO_4$ would be compatible with the sample prior to requesting the laboratory to add it to the sample.

3. Regional Quality Assurance Project Plans (QAPPs) may require the use of Option 6. Note that this option is for medium-level analysis ONLY.
4. If water, methanol, or $NaHSO_4$ preservative is added to the vials in the field, a field blank containing the appropriate preservative used in the vials should be sent to the laboratory for analysis.

This page is intentionally left blank.

APPENDIX D CLP SAMPLE COLLECTION REQUIREMENTS BY ANALYSIS TYPE

The following tables (D-1 through D-4) specify the number of containers of each type necessary for each analysis based on the sampling methodology and QC requirements.

Table D-1. Sample Collection Requirements for CLP Organics [Volatile Organic Analytes (VOAs) Only]

Analysis	Matrix	Sample Type	Container Type[1]	Closure[2]	Minimum Number of Containers Needed				Minimum Volume/Mass[3]	Important Notes	Preservative[4]	Technical Holding Time[5]
					with Water	Dry	% Moisture	TOTAL				
VOAs	Water	Samples Only	40 mL amber or clear glass vial, 24 mm neck finish.	Polypropylene or phenolic, open-top screw-cap, 1.5 cm opening, 24-400 size.	-	-	-	**4**	Fill to capacity	Containers/vials must be filled to capacity with no headspace or air bubbles. Refer to Appendix B for samples requiring QC analyses. If amber containers are not available, the samples should be protected from light.	Preserve to a pH of 2 with HCl and cool to ≤ 6°C, but not frozen, immediately after collection. DO NOT FREEZE water samples.	14 days
		Samples with SIM			-	-	-	**6**				
		Samples with Matrix Spike (MS)/MS Duplicate (MSD)[6]			-	-	-	**8**				
	Soil/ Sediment	Samples Only	**OPTION 1** Closed-system 40 mL amber or clear glass vial containing magnetic stirrer, 24 mm neck finish.	Polypropylene or phenolic, open-top screw-cap, 1.5 cm opening, 24-400 size.	-	3	1	**4**	5g	Place samples on side prior to being iced.[7] Refer to Appendix C for samples requiring QC analyses.	Frozen to < -7°C **OR** Iced to ≤ 6°C, but not frozen.	14 days **OR** 48 hours (unpreserved)[7]
		Samples with MS/MSD[6]			-	11	1	**12**				
		Samples Only	**OPTION 2** Closed-system 40 mL amber or clear glass vial containing magnetic stirrer, 24 mm neck finish and 5 mL water.	Polypropylene or phenolic, open-top screw-cap, 1.5 cm opening, 24-400 size.	3	-	1	**4**	5 g	Place samples on side prior to being iced.[7] Refer to Appendix C for samples requiring QC analyses.	Frozen to < -7°C **OR** Iced to ≤ 6°C, but not frozen.	14 days **OR** 48 hours (unpreserved)[7]
		Samples with MS/MSD[6]			11	-	1	**12**				

Table D-1. (Continued) Sample Collection Requirements for CLP Organics [Volatile Organic Analytes (VOAs) Only]

Analysis	Matrix	Sample Type	Container Type[1]	Closure[2]	Minimum Number of Containers Needed				Minimum Volume/Mass[3]	Important Notes	Preservative[4]	Technical Holding Time[5]
					with Water	Dry	% Moisture	TOTAL				
		Samples Only	**OPTION 3** Coring tool used as a transport device.		-	3	1	**4**	5 g	Refer to Appendix C for samples requiring QC analysis. Place samples on side prior to being iced.[7]	Frozen to < -7°C **OR** Iced to ≤ 6°C, but not frozen.	14 days (frozen) **OR** 48 hours (iced)[7]
		Samples with MS/MSD[6]			-	11	1	**12**				
		Samples for TCLP/SPLP Only	**OPTION 4** Closed-system 40 mL amber or clear glass vial 24 mm neck finish.	Polypropylene or phenolic, open-top screw-cap, 1.5 cm opening, 24-400 size.	-	6	-	**6**	150 g[8]	Place samples on side prior to being iced.[7]	Iced to ≤ 6°C but not frozen.	14 days

Notes

1 Vials for soil analysis are typically pre-labeled and tared. Vials for water analysis are not pre-labeled or tared.

2 Septums for VOA vials 24 mm disc of Polytetrafluoroethylene (PTFE) bonded to silicone for a total thickness of 0.100 - 0.125 in.

3 Minimum volume/mass to be collected in order to ensure sample analysis can be performed. Collect additional volume for MS/MSD samples to allow for sufficient volume for these analyses in the event sample volume is lost as a result of sample containers breaking, leaking, or laboratory accidents.

4 Check Regional guidance regarding use of acid as a preservative of samples that may contain carbonates, residual chlorine, and other oxidants.

5 Technical holding time is calculated from the time of sample collection to sample extraction, and determined as 14 days for preserved (frozen or iced) samples and 48 hours for non-preserved (iced) samples.

6 For Gas Chromatograph/Mass Spectrometer (GC/MS) organic analyses, a Region may decide to reference Deuterated Monitoring Compounds (DMCs) rather than MS/MSD for accuracy and precision.

7 Vials are placed on their side so that the septum is wet on the inside, thereby preventing vapor leaks around it, in case any bubbles form. Also, in case samples freeze, the water will expand into the flexible septum rather than breaking the vial.

8 Samples with low solids content that are scheduled for Toxicity Characteristic Leaching Procedure (TCLP) or Synthetic Precipitation Leaching Procedure (SPLP) may require up to 1000 mL total volume.

Table D-2. Sample Collection Requirements for CLP Organics [Semivolatile Organic Analytes (SVOAs), Pesticides, and Aroclors]

Analysis	Matrix	Sample Type	Container Type	Closure	Minimum Volume/Mass[1]	Important Notes	Preservative/ Collection	Technical Holding Time[2]
SVOAs	Water[3]	Samples Only	1 L amber round glass bottle, 33 mm pour-out neck finish.	Polypropylene or phenolic cap, 33-430 size; 0.015 in. PTFE liner.	2 L (per Test)	If amber containers are not available, the samples should be protected from light.	Cool all samples to ≤ 6°C, but not frozen, immediately after collection. DO NOT FREEZE water samples.	7 days
		Samples with SIM			2 L			
		Samples with MS/MSD			5 L			
		Samples with SIM with MS/MSD			5 L			
	Soil/ Sediment/ Waste[4]	Samples Only	One 8 oz. short, wide mouth, straight-sided, glass jar, 70 mm neck finish or two 4 oz. tall, wide mouth, straight-sided, glass jar, 48 mm neck finish.	Polypropylene or phenolic cap, 70-400 size; 0.015 in. PTFE liner. Or Polypropylene or phenolic cap, 48-400 size; 0.015 in. PTFE liner.	150 g		Cool all samples to ≤ 6°C, but not frozen, immediately after collection.	14 days
		Samples with SIM						
		Samples with MS/MSD	Two 8 oz. short, wide mouth, straight-sided, glass jars, 70 mm neck finish or three 4 oz. tall, wide mouth, straight-sided, glass jar, 48 mm neck finish.		300 g			
		Samples with SIM with MS/MSD						
		Samples for Only TCLP/SPLP	Two 8 oz. short, wide mouth, straight-sided, glass jars, 70 mm neck finish or four 4 oz. tall, wide mouth, straight-sided, glass jar, 48 mm neck finish.		450 g			

Table D-2. (Continued) Sample Collection Requirements for CLP Organics [Semivolatile Organic Analytes (SVOAs), Pesticides, and Aroclors]

Analysis	Matrix	Sample Type	Container Type	Closure	Minimum Volume/Mass[1]	Important Notes	Preservative/ Collection	Technical Holding Time[2]
Pesticides	Water[3, 5]	Samples Only	1 L amber round glass bottle, 33 mm pour-out neck finish.	Polypropylene or phenolic cap, 33-430 size; 0.015 in. PTFE liner.	2 L	If amber containers are not available, the samples should be protected from light.	Cool all samples to ≤ 6°C, but not frozen, immediately after collection. DO NOT FREEZE water samples.	7 days
		Samples with MS/MSD			5 L			
	Soil/ Sediment/ Waste[4]	Samples Only	One 8 oz. short, wide mouth, straight-sided, glass jar, 70 mm neck finish or two 4 oz. tall, wide mouth, straight-sided, glass jar, 48 mm neck finish.	Polypropylene or phenolic cap, 70-400 size; 0.015 in. PTFE liner. Or Polypropylene or phenolic cap, 48-400 size; 0.015 in. PTFE liner.	150 g		Cool all samples to ≤ 6°C, but not frozen, immediately after collection.	14 days
		Samples with MS/MSD	Two 8 oz. short, wide mouth, straight-sided, glass jars, 70 mm neck finish or three 4 oz. tall, wide mouth, straight-sided, glass jar, 48 mm neck finish.		300 g			
		Samples for Only TCLP/SPLP	Two 8 oz. short, wide mouth, straight-sided, glass jars, 70 mm neck finish or four 4 oz. tall, wide mouth, straight-sided, glass jar, 48 mm neck finish.		450 g			
	Wipes	Samples Only	20 mL glass vial.	Polypropylene or phenolic cap, PTFE liner.	1 wipe			14 days
Aroclors	Water[3, 5]	Samples Only	1 L amber round glass bottle, 33 mm pour-out neck finish.	Polypropylene or phenolic cap, 33-430 size; 0.015 in. PTFE liner.	2 L	If amber containers are not available, the samples should be protected from light.	Cool all samples to ≤ 6°C, but not frozen, immediately after collection. DO NOT FREEZE water samples.	7 days
		Samples with MS/MSD			5 L			
	Soil/ Sediment/ Waste[4]	Samples Only	One 8 oz. short, wide mouth, straight-sided, glass jar, 70 mm neck finish or two 4 oz. tall, wide mouth, straight-sided, glass jar, 48 mm neck finish.	Polypropylene or phenolic cap, 70-400 size; 0.015 in. PTFE liner. Or Polypropylene or phenolic cap, 48-400 size; 0.015 in. PTFE liner.	150 g		Cool all samples to ≤ 6°C, but not frozen, immediately after collection.	14 days
		Samples with MS/MSD	Two 8 oz. short, wide mouth, straight-sided, glass jars, 70 mm neck finish or three 4 oz. tall, wide mouth, straight-sided, glass jar, 48 mm neck finish.		300 g			
	Wipes	Samples Only	20 mL glass vial.	Polypropylene or phenolic cap, PTFE liner.	1 wipe			14 days

Table D-2. (Continued) Sample Collection Requirements for CLP Organics [Semivolatile Organic Analytes (SVOAs), Pesticides, and Aroclors]

Notes

1 Minimum volume/mass to be collected in order to ensure sample analysis can be performed.

2 This technical holding time is calculated from the time of sample collection to sample extraction. Sample extracts are to be analyzed within 40 days of extraction. It is recommended that samplers ship samples to the laboratory on the same day that they are collected, or as soon as possible thereafter.

3 An aqueous sample for SVOA analysis would require the field sampler to collect at least 2 L for field samples and at least 3 L for the MS and MSD samples for a total volume of 5 L. If Pesticide or Aroclor MS/MSD analyses are required for the same sample, only two extra 1 L bottles of each sample would be needed, for a total of seven bottles (which includes samples and MS/MSD for both methods). Collect additional volume for MS/MSD samples to allow for sufficient volume for these analyses in the event sample volume is lost as a result of sample containers breaking, leaking, or laboratory accidents.

4 If one or two extractable analyses are required for soil/sediment, only a single 8 oz. or two 4 oz. jars are required. If three extractable analyses are required, two 8 oz. or four 4 oz. jars are required. The number of jars should be doubled if MS/MSD is required.

5 Samplers must test for chlorine in aqueous samples in the field upon collection. Refer to the Sampling and Analysis Plan (SAP) and Appendix E of this document for guidance.

Table D-3. Sample Collection Requirements for CLP Inorganics

Analysis	Matrix	Sample Type	Container Type	Closure	Minimum Volume/ Mass[1]	Important Notes	Preservative/ Collection[2]	Technical Holding Time[3]
Metals/ICP-AES, Metals/ICP-MS, and/or Mercury/CVAA	Water	Samples Only	0.5 L high density polyethylene, cylinder-round bottle, 28 mm neck finish.	Polyethylene cap, ribbed, 28-410 size; F217 polyethylene liner.	0.5 L	DO NOT FREEZE water samples.	Acidify to pH < 2 with HNO_3 immediately after collection.[4]	6 months for all metals except Mercury (28 days)
		Samples with MS/Duplicate			1 L			
	Soil/ Sediment/ Waste[5]	Samples Only	One 8 oz. short, wide mouth, straight-sided, glass jar, 70 mm neck finish.	Polypropylene or phenolic cap, 70-400 size; 0.015 in. PTFE liner.	Fill to capacity		Cool to ≤ 6°C, but not frozen, immediately after collection.	6 months
		Samples with MS/Duplicate						
		Samples for Only TCLP/SPLP	Two 8 oz. short, wide mouth, straight-sided, glass jars, 70 mm neck finish.					
Metals/ICP-AES[6]	Wipe	Samples Only	1 qt. polymer zip-top bag.	Has self-closing mechanism.	N/A		Store at room temperature.	6 months
Cyanide/ Spectrophotometric Determination	Water	Samples Only	0.5 L high density polyethylene, cylinder-round bottle, 28 mm neck finish.	Polyethylene cap, ribbed, 28-410 size; F217 polyethylene liner.	0.5 L	DO NOT FREEZE water samples.	To neutralize residual chlorine, add 0.6 g ascorbic acid for each liter of sample collected, immediately upon collection.[7] Add NaOH until pH > 10 and cool to ≤ 6°C, but not frozen, immediately after collection.	14 days
		Sample with MS/Duplicate			1 L			
	Soil/ Sediment/ Waste[5]	Samples Only	One 8 oz. short, wide mouth, straight-sided, glass jar, 70 mm neck finish.	Polypropylene or phenolic cap, 70-400 size; 0.015 in. PTFE liner.	Fill to capacity		Cool to ≤ 6°C, but not frozen, immediately after collection.	14 days
		Samples with MS/Duplicate						
		Samples for SPLP						

Table D-3. (Continued) Sample Collection Requirements for CLP Inorganics

Analysis	Matrix	Sample Type	Container Type	Closure	Minimum Volume/ Mass[1]	Important Notes	Preservative/ Collection[2]	Technical Holding Time[3]
Anions/Ion Chromatography (IC)[8]	Water	Samples Only	125 mL high density polyethylene, cylinder-round bottle, 28 mm neck finish.	Polyethylene or polypropylene cap, ribbed.	125 mL	DO NOT FREEZE water samples.	For the analysis of nitrate, nitrite, orthophosphate, and sulfate cool to ≤ 6°C, but not frozen, immediately after collection. Do not allow samples for orthophosphate to be held at room temperature more than 12 hours.	48 hours for nitrate, nitrite, and orthophosphate. 28 days for bromide, chloride, fluoride, and sulfate.
		Samples with MS/Duplicate			250 mL			
	Soil	Samples Only	One 8 oz. short, wide mouth, straight-sided, glass jar, 70 mm neck finish.	Polypropylene or phenolic cap, 70-400 size; 0.015 in. PTFE liner.	Fill to capacity		Cool to ≤ 6°C, but not frozen, immediately after collection.	48 hours for nitrate, nitrite, and orthophosphate. 28 days for bromide, chloride, fluoride, and sulfate.
		Samples with MS/Duplicate						
Hexavalent Chromium/Ion Chromatography (IC)[8]	Water	Samples Only	125 mL high density polyethylene or polypropylene, cylinder-round bottle, 28 mm neck finish.	Polyethylene or polypropylene cap, ribbed.	125 mL	DO NOT FREEZE water samples.	Cool to ≤ 6°C, but not frozen, immediately after collection. Field filter. Preserve to pH > 8 using either liquid preservative [NH_4OH/$(NH_4)_2SO_4$ 1 mL per 100 mL sample] or solid mix [13.3 mg Na_2CO_3/10.5 mg $NaHCO_3$/33 mg $(NH_4)_2SO_4$ per sample].	28 days
		Samples with MS/Duplicate			250 mL			
Total Organic Carbon (TOC)[8]	Water	Samples Only	125 m L round glass bottle, 22 mm pour-out neck finish.	Polypropylene or phenolic cap, PTFE liner.	125 mL	DO NOT FREEZE water samples.	Acidify to pH < 2 with H_2SO_4 or H_3PO_4 immediately after collection and cool to ≤ 6°C, but not frozen.	28 days
		Samples with MS/Duplicate			250 mL			
	Soil	Samples Only	4 oz. (120 mL) tall, wide mouth, straight-sided, amber glass jar, 48 mm neck finish.	Polypropylene or phenolic cap, 48-400 size; 0.015 in. PTFE liner.	Fill to capacity		Cool to ≤ 6°C, but not frozen, immediately after collection.	28 days
		Samples with MS/Duplicate						

Table D-3. (Continued) Sample Collection Requirements for CLP Inorganics

Notes

1 Minimum volume/mass to be collected in order to ensure sample analysis can be performed.
2 Check Regional guidance regarding use of acid as a preservative of samples that may contain carbonates, residual chlorine, and other oxidants.
3 This technical holding time is calculated from the time of sample collection to sample analysis.
4 Water samples collected for total metal and filtered metal analyses from the same sampling location must be assigned separate (unique) CLP Sample Numbers.
5 Only one 8 oz. jar is needed for soil/sediment when all metals (including mercury) and cyanide analyses are required for soil/sediment samples. Collect more than one jar when TCLP or SPLP are scheduled.
6 Wipe materials have varied from laboratory tissues (e.g., Kimwipes®) to pre-moistened “baby wipes” from the nearest store.
7 Samplers must test for sulfide and oxidizing agents (e.g., chlorine) in aqueous samples in the field upon collection. Refer to the SAP for guidance. Sulfides adversely affect the analytical procedure. The following can be done to test for and neutralize sulfides. Place a drop of the sample on lead acetate test paper to detect the presence of sulfides. If sulfides are present, treat 25 mL more of the sample than that required for the cyanide determination with powdered cadmium carbonate or lead carbonate. Yellow cadmium sulfide or black lead sulfide precipitates if the sample contains sulfide. Repeat this operation until a drop of the treated sample solution does not darken the lead acetate test paper. Filter the solution through a dry filter paper into a dry beaker, and from the filtrate measure the sample to be used for analysis. Avoid a large excess of cadmium carbonate and a long contact time in order to minimize a loss by complication or occlusion of cyanide on the precipitated material. Sulfide removal should be performed in the field, if practical, prior to pH adjustment with NaOH.
8 Analyses available through Modified Analysis only.

Table D-4. Sample Collection Requirements for CLP Chlorinated Dibenzo-*p*-Dioxins/Chlorinated Dibenzofurans (CDDs/CDFs) and Chlorinated Biphenyl Congeners (CBCs)

Analysis	Matrix	Container Types	Closure	Minimum Volume/Mass[1]	Important Notes	Preservative	Technical Holding Time[2]
CDD/CDF and CBC	Water[3]	1 L amber round glass bottle, 33 mm pour-out neck finish.	Polypropylene or phenolic cap, 33-430 size; 0.015 in. PTFE liner.	2L	If amber containers are not available, the samples should be protected from light.	Cool all samples to ≤ 6°C, but not frozen, immediately after collection. DO NOT FREEZE water samples. If residual chlorine is present, add 80 mg sodium thiosulfate/L of water. If pH is greater than 9, adjust to 7-9 with sulfuric acid.	1 year
	Soil/Sediment/Oil/ Sludge Ash/Biosolids	8 oz. short, wide mouth, straight-sided, glass jar, 70 mm neck finish or 4 oz. (120 mL) tall, wide mouth, straight-sided, amber glass jar, 48 mm neck finish.	Polypropylene or phenolic cap, 70-400 size; 0.015 in. PTFE liner. Or Polypropylene or phenolic cap, 48-400 size; 0.015 in. PTFE liner.	Fill to capacity	If amber containers are not available, the samples should be protected from light.	Cool all samples to ≤ 6°C, but not frozen, immediately after collection.	
	Tissue	Heavy duty aluminum foil as transport device. 8 oz. short, wide mouth, straight-sided, glass jar, 70 mm neck finish or 4 oz. (120 mL) tall, wide mouth, straight-sided, amber glass jar, 48 mm neck finish.	Polypropylene or phenolic cap, 70-400 size; 0.015 in. PTFE liner. Or Polypropylene or phenolic cap, 48-400 size; 0.015 in. PTFE liner.	20 g for each analytical method	If amber containers are not available, the samples should be protected from light.	Cool all samples to ≤ 6°C, or freeze immediately after collection.	

Notes

1 Minimum volume/mass to be collected in order to ensure sample analysis can be performed.

2 This technical holding time is calculated from the time of sample collection to sample extraction. Sample extracts are to be analyzed within 1 year of extraction when sample extracts are stored under the appropriate conditions. It is recommended that samplers ship samples to the laboratory on the same day that they are collected, or as soon as possible thereafter.

3 Samplers must test for chlorine in aqueous samples in the field upon collection. Refer to the SAP for guidance.

This page is intentionally left blank.

APPENDIX E SAMPLING TECHNIQUES AND CONSIDERATIONS

During a sampling event, samplers are expected to follow prescribed sampling techniques. Samplers should also be aware of any special sampling considerations, contaminant issues, and sample compositing and mixing methods that could affect their sampling efforts.

Regional guidance will take precedence over any of the techniques and considerations listed below.

1. General Sampling Techniques

Information regarding surface water, groundwater, sediment, soil, and surface wipe sampling can be found in many documents including, but not limited to, the following sources:

- *Compendium of ERT Surface Water and Sediment Sampling Procedures*, EPA/540/P-91/005
- *Compendium of ERT Soil Sampling and Surface Geophysics Procedures*, EPA/540/P-91/006
- *Compendium of ERT Groundwater Sampling Procedures*, EPA/540/P-91/007
- *The Roles of Project Managers and Laboratories in Maintaining the Representativeness of Incremental and Composite Soil Samples*, EPA/OSWER 9200.1-117FS
- *Lead in Surface Wipe Samples*, NIOSH Method 9100, August 15, 1994
- *Elements on Wipes*, NIOSH Method 9102, March 15, 2003
- *Surface Wipe Sampling Procedure*, IH75190, Brookhaven National Laboratory, Industrial Hygiene Group, May 10, 2011

When working with potentially hazardous materials, samplers should follow U.S. Environmental Protection Agency (EPA) and Occupational Health and Safety Administration (OSHA) requirements, specific health and safety procedures, and Department of Transportation (DOT) requirements.

2. Special Sampling Considerations

Samplers should refer to the Regional Standard Operating Procedures (SOPs) to obtain specific procedures for proper collection and preservation of samples in the field. For additional guidance regarding sampling for Volatile Organic Analytes (VOAs) Analysis in soil and water, see Appendices B and C. Samplers should obtain Regional guidance when testing and ameliorating for:

- Carbonates in VOA soil and water samples
- Residual chlorine in VOA soil and water samples, or in aqueous cyanide samples
- Oxidants in VOA soil and water samples
- Sulfides and oxidizing agents in aqueous cyanide samples

3. Contaminant Sampling

Certain analytes can be detected in the parts-per-billion (ppb) and/or parts-per-trillion (ppt) range. Extreme care MUST be taken to prevent cross-contamination of these samples. The following precautions should be taken when trace contaminants are a concern:

- Disposable gloves should be worn for each different location sampled.
- When collecting both surface water and sediments, surface water samples should be collected first to reduce the chance of sediment dispersal into the surface water, and the resulting loss of surface water sample integrity.

- Sampling should occur progressively, from the least to the most contaminated area, if this information is known to the sampling team.
- Samplers should use equipment constructed of polytetrafluoroethylene (PTFE), stainless steel, or glass that has been properly pre-cleaned for the collection of samples for trace organic and/or inorganic analyses. Equipment constructed of plastic or polyvinyl chloride (PVC) should NOT be used to collect samples for trace organic analyte analyses.
- Equipment constructed of stainless steel should NOT be used to collect samples for trace metals analyses.

4. Sample Compositing

Sample compositing is a site-specific activity that must be conducted according to the Sampling and Analysis Plan (SAP). Compositing is typically used for large sites to improve the precision (i.e., lower the variance) of the estimated average contaminant concentrations. **Samples for VOA analysis should NOT be composited to minimize loss of analytes.**

Composite samples consist of a series of discrete grab samples that are mixed together to characterize the average composition of a given material. The discrete samples are usually of equal volume, but may be weighted to reflect an increased flow or volume. Nevertheless, all discrete samples must be collected in an identical manner and the number of grab samples forming a composite should be consistent. There are several compositing techniques that may be required, such as:

- Flow-proportioned - Collected proportional to the flow rate during the compositing period by either a time-varying/constant volume or a time-constant/varying volume method. This technique is usually associated with wastewater or storm water runoff sampling.
- Time - Composed of a varying number of discrete samples collected at equal time intervals during the compositing period. This technique is typically used to sample wastewater and streams, and in some air sampling applications.
- Areal - Collected from individual grab samples collected in an area or on a cross-sectional basis. Areal composites are comprised of equal volumes of grab samples where all grabs are collected in an identical manner. This technique is typically used for estimating average contaminant concentrations in soils or sediments. It is also useful when contaminants are present in nugget form (i.e., TNT chunks, lead shot, etc.), thus exhibiting large differences in concentration over a small sample area.
- Vertical - Collected from individual grab samples taken from a vertical cross section. Vertical composites are comprised of equal volumes of grab samples where all grab samples are collected in an identical manner. Examples would include vertical profiles of a soil borehole or sediment columns.
- Volume - Collected from discrete samples whose aliquot volumes are proportional to the volume of sampled material. Volume composites are usually associated with hazardous waste bulking operations where the sample represents combined or bulked waste.

When compositing solid or tissue samples (i.e., sediment, soil, or sludge) for analysis of analytes present in trace quantities, use a stainless steel or PTFE bowl and spatula as applicable.

5. Sample Mixing and Homogenizing

Mixing of the sample for the remaining parameters is necessary to create a representative sample media. It is extremely important that solid samples be mixed as thoroughly as possible to ensure that the sample is representative of the sample location. Refer to the project-specific SAP for instructions on removal of any extraneous materials (e.g., leaves, sticks, rocks, etc.). The mixing technique will depend on the physical characteristics (e.g., particle size, moisture content, etc.) of the solid material. For example, grinding and homogenization of tissue is easier when it is partially frozen. The mixing container should be large enough to hold the sample volume and accommodate the procedures without spilling. Both the mixing container (generally a bowl or tray) and the mixing implement should be properly decontaminated before use. Samples should be homogenized

according to procedures listed in the project-specific SAP. Table E-1 provides a brief procedure for mixing a soil sample with a small particle size (less than 1/4 in.) and filling sample containers in the field.

Table E-1. Mixing a Sample and Filling Sample Containers

Step	Action
1	Roll the contents of the compositing container to the middle of the container and mix.
2	Quarter the sample and move to the sides of the container.
3	Mix each quarter individually, then combine and mix OPPOSITE quarters, then roll to the middle of the container.
4	Mix the sample once more, and then quarter the sample again.
5	Mix each quarter individually, then combine and mix ADJACENT corners, then roll to the middle of the container. The goal is to achieve a consistent physical appearance before sample containers are filled.
6	Flatten piled material into an oblong shape.
7	Using a flat-bottomed scoop, collect a strip of soil across the entire width of the short axis and place it into a sample container.
8	Repeat Step 7 at evenly-spaced intervals until the sample containers are filled.
9	Record the approximate quantity of each subsample in the field logbook.

This page is intentionally left blank.

APPENDIX F INTERNATIONAL SHIPPING

The following section provides information on shipping Contract Laboratory Program (CLP) samples to laboratories outside the United States.

F.1 United Parcel Service (UPS) Procedure for Shipping to Canada

1. Introduction

Samplers should refer to the Standard Operating Procedure (SOP) for the responsibilities and procedures for shipping to Canadian laboratories. The following sections detail the export shipping process.

2. Overview

UPS will provide pick-up and delivery service for small package (weighing less than 150 lbs. each) shipments to laboratories in Canada.

3. Contact Information

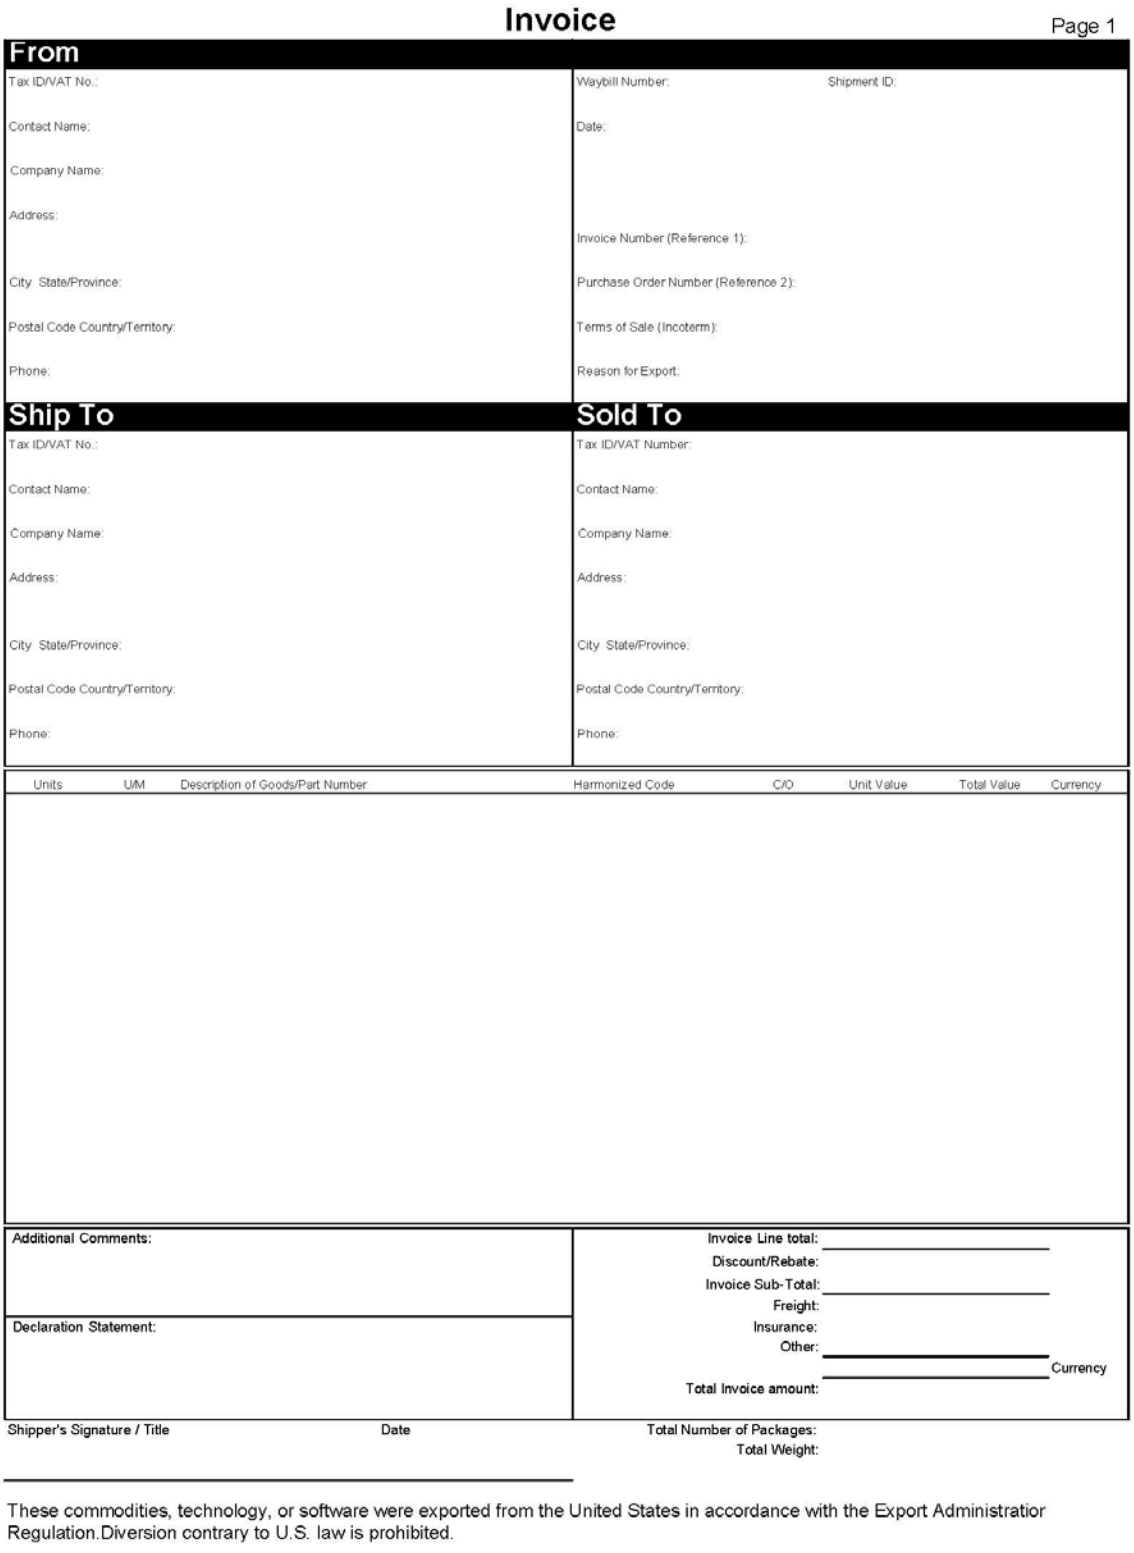
UPS Strategic Support for Government Accounts	https://www.ups.com/us/en/services/government.page
UPS International Customer Service	www.ups.com/international
Preferred Customer Associate Team	https://www.ups.com/us/en/help-support-center.page?

4. Customs Broker

The laboratory should be notified of each shipment so they know to contact their customs broker to have the shipment released. Otherwise, shipments may be held in customs. Laboratories may also act as their own broker.

5. Product Profile

Service Level – EPA receives government pricing for shipments via UPS *Worldwide Express Saver* service. This service provides guaranteed delivery within 1 – 3 business days, by end of day, to Canada. The maximum weight per package is 150 lbs. (70 kg), maximum length is 108 in. (270 cm) per package and the maximum dimensions are 165.0 in. (419.10 cm) per package, length and girth combined.



6. Commercial Invoice

A commercial invoice form (see Figure F-1) is used for all shipments containing non-documents. It is the primary document used for importation control, valuation, and duty determination. This document identifies the items in the shipments.

The form should include:

- Complete name and address information for both shipper and consignee
- Phone numbers for shipper and consignee
- Terms of Sale (Incoterm)
- Reason for export
- A complete description of the item
- Type of item
- Item use
- Harmonized Tariff Codes, if known

- Country of origin (where manufactured) for each commodity
- Number of units, unit value, and total value (purchase price) of each item
- Number of packages and total weight
- Shipper’s signature and date
- A nominal or fair market value must be stated for items of no commercial value

7. Packing with Coolants and Refrigerants (Dry Ice)

Coolants and refrigerants are used to keep temperature-sensitive items cold or frozen while in transit. Dry ice (frozen carbon dioxide) and ice are the most common types of coolant/refrigerants used for transportation.

International Air Shipments Containing Dry Ice

International Air shipments containing dry ice require the shipper to have a UPS International Special Commodities contract. For additional information, please contact the UPS Hazardous Materials Support Center at 1-800-554-9964, or visit our online UPS Guide for Shipping International Dangerous Goods.

https://www.ups.com/us/en/help-center/packaging-and-supplies/special-care-shipments/international-dangerous-goods/shippers-responsibilities.page

International Dry Ice Packages Shipped via Air Service Require the Following Under International Air Transport Association (IATA):

- Process through WorldShip 2019, CampusShip, or compliant software
- An acceptance audit is performed
- Mark the outer carton with:
  - The words “Dry Ice” of “Carbon Dioxide, Solid” and “UN 1845”
  - The amount of dry ice contained in the package in kg
  - Class 9 Diamond label

Requirements for Preparing Dry Ice Shipments:

- Fill any empty space in the shipping container with appropriate packing material to prevent product movement during transit.
- Wrap temperature-sensitive products in two watertight plastic bags or use absorbent material along with a plastic liner.
- Avoid shipping temperature-sensitive products over the weekend.
- Wrap the refrigerant in paper or another carton to slow the sublimation rate and prevent excess space when using dry ice.
- Do not place the refrigerant at the bottom of the package because cold air will not circulate.
- Do not seal the inner insulated container when using dry ice. Venting is required to allow some carbon dioxide gas to escape the package.

* UPS CampusShip is a web-based, UPS-hosted shipping solution that helps to increase efficiency and reduce costs.

8. Additional Information

Common items that may be hazardous require the shipper to have a UPS International Special Commodities contract. For additional information, contact the UPS Hazardous Materials Support Center at 1-800-554-9964, or visit the online UPS Guide for Shipping International Dangerous Goods.

Descriptions that Indicate Dangerous Goods – watch for any of the following descriptions that could indicate Dangerous Goods or Hazardous Materials:

- Acidic
- Caustic
- Combustible Communicable
- Compressed Gas
- Corrosive
- Explosive
- Flammable
- Infectious
- Inflammable

- Poison
- Radioactive
- Refrigerated
- Toxic
- Volatile

Note: The above is only a sampling of terms which should prompt further questions about a shipment.

9. Tools and Resources

UPS Global

Access UPS Global website to get up-to-date information on everything international, including information on how to prepare an international shipment, track your package, and import/export country regulations and international forms.

Processing International Package using UPS CampusShip

https://www.ups.com/media/en/CampusShip_shipping_QuickStart_Guide.pdf

Step-by-Step Instructions for International Shipping

Step 1. Verify That The Commodity Can Be Shipped

Determine if service restrictions apply to either the United States or Canada.

Check for Embargoed/Suspended Service

Verify that your commodity can be shipped to or from the United States and Canada.

Check List of UPS Export Prohibited Articles

Step 2. Select an International Service If price and time are your primary considerations in selecting an international service, use the Service Comparison tool on UPS CampusShip to find the guaranteed delivery time and price of every service available to and from the United States and Canada.

Step 3. Select an International Billing Option

UPS offers flexible international billing options. Select the applicable option.

Learn More About International Billing Options

Step 4. Create Required Documentation

Determine the export documentation required for the shipment and complete each form.

Learn How to Create Documentation

Step 5. Prepare The Shipment

Use UPS International Shipping Basics to learn more about preparing your shipment.

Learn What Packing Materials to Use for Your International Shipment

Identify Specific Weight and Size Limitations Convert the Weight, Length, Area, and Volume of Your Shipment

Decide whether to declare a value for high value items. If the value of the goods exceeds $100.00 (USD), declare a higher value, up to $50,000.00 (USD) per package. For packages that exceed the maximum declared value, a waiver must be obtained. Refer to the applicable terms and conditions of service for additional limits and restrictions.

Learn More About Declared Value

Step 6. Ship The Package

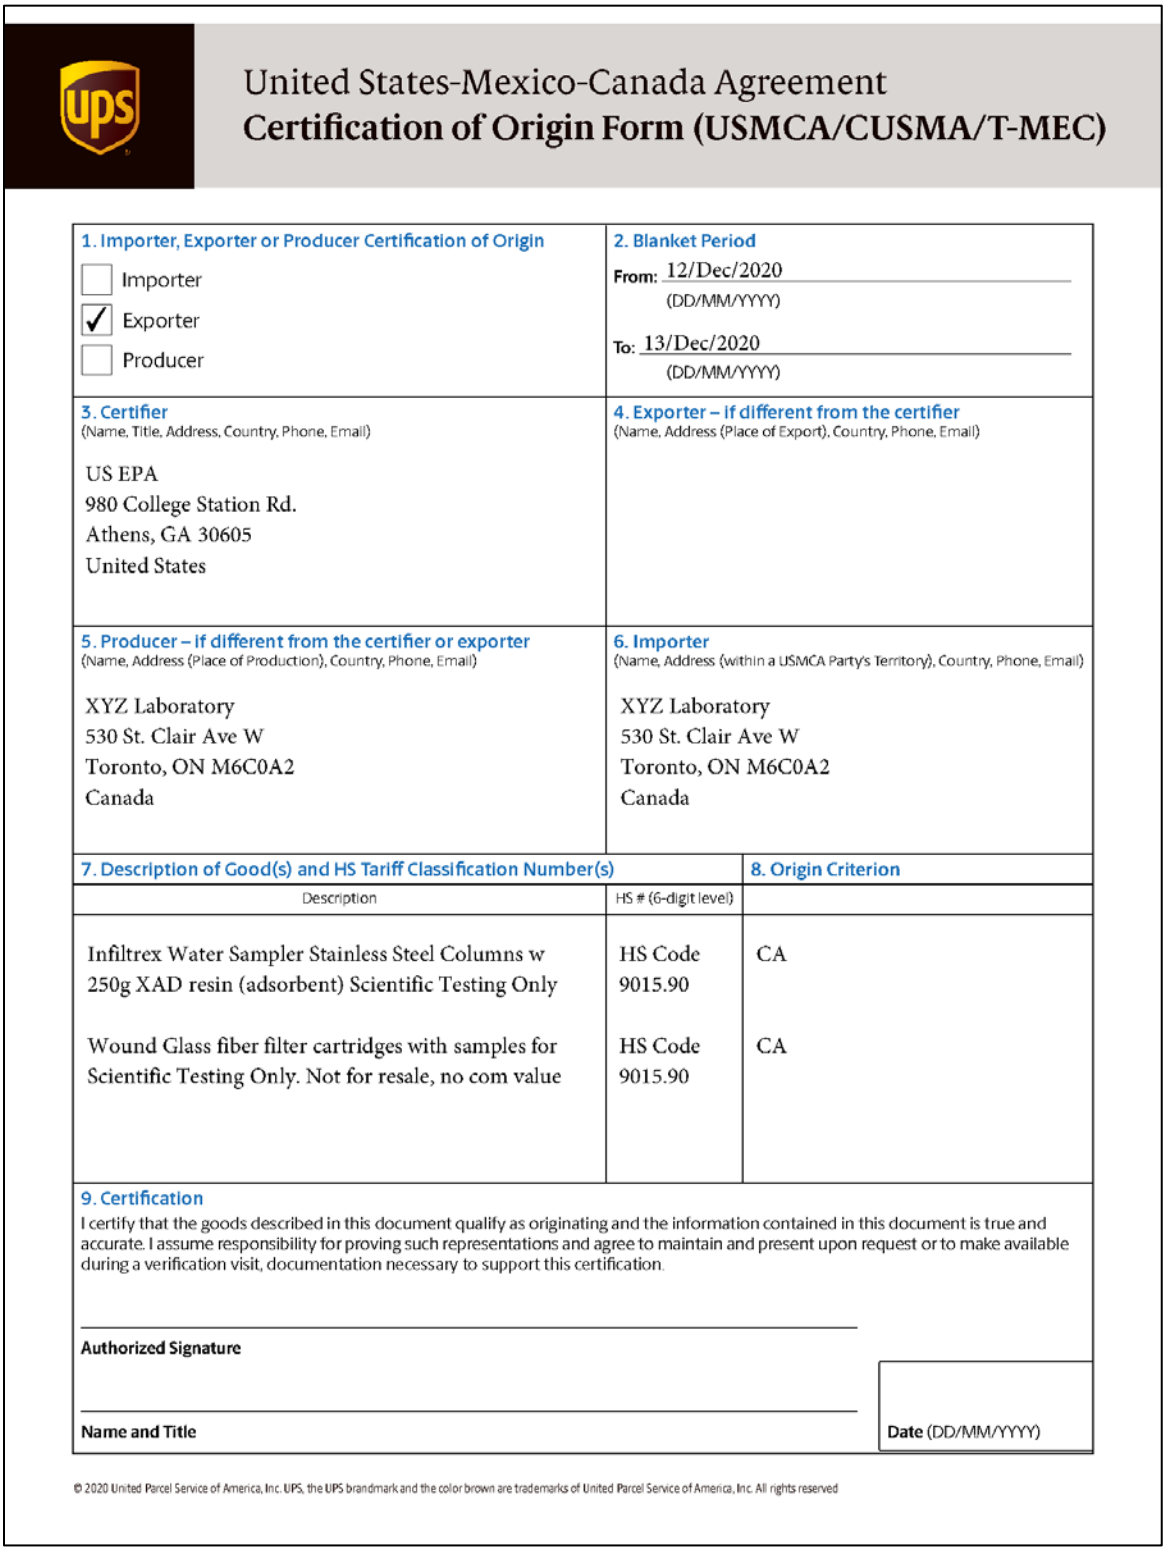
Use UPS CampusShip or Internet Shipping on ups.com to prepare the international shipping label and the international forms required for certain shipments.

Step 7. Get The Shipment to UPS

In instances where automatic pickup has not been scheduled, UPS On-Call Pickup® may be requested to pick up all ground, air, and international shipments from any location. UPS On-Call Pickup can be scheduled at ups.com or by calling 1-800-PICK-UPS® for same day or future day pickup. Packages can also be shipped from UPS locations including The UPS Store®.

Find Locations

Step 8. Check Shipment Status



Since each UPS package is assigned a unique tracking number, shipment information is easily accessible. Tracking information is always available at ups.com, by e-mail, and through optional services.

Track Your Shipment

Learn About More Ways to Track

F.2 Completed Customs Forms Example

Shipping samples to an international laboratory requires the completion of a customs form. The following is an example of a correctly completed customs form for shipment to a laboratory in Canada.

United States-Mexico-Canada Agreement
Certification of Origin Form (USMCA/CUSMA/T-MEC)

1. Importer, Exporter or Producer Certification of Origin

- ☐ Importer
- ☑ Exporter
- ☐ Producer

2. Blanket Period

From: 12/Dec/2020 (DD/MM/YYYY)

To: 13/Dec/2020 (DD/MM/YYYY)

3. Certifier
(Name, Title, Address, Country, Phone, Email)

US EPA
980 College Station Rd.
Athens, GA 30605
United States

4. Exporter – if different from the certifier
(Name, Address (Place of Export), Country, Phone, Email)

5. Producer – if different from the certifier or exporter
(Name, Address (Place of Production), Country, Phone, Email)

XYZ Laboratory
530 St. Clair Ave W
Toronto, ON M6C0A2
Canada

6. Importer
(Name, Address (within a USMCA Party's Territory), Country, Phone, Email)

XYZ Laboratory
530 St. Clair Ave W
Toronto, ON M6C0A2
Canada

7. Description of Good(s) and HS Tariff Classification Number(s)

Description	HS # (6-digit level)	8. Origin Criterion
Infiltrex Water Sampler Stainless Steel Columns w 250g XAD resin (adsorbent) Scientific Testing Only	HS Code 9015.90	CA
Wound Glass fiber filter cartridges with samples for Scientific Testing Only. Not for resale, no com value	HS Code 9015.90	CA

9. Certification

I certify that the goods described in this document qualify as originating and the information contained in this document is true and accurate. I assume responsibility for proving such representations and agree to maintain and present upon request or to make available during a verification visit, documentation necessary to support this certification.

Figure F-3. International Shipping Form (2 of 3)

Certification of Origin Form (USMCA/CUSMA/T-MEC) Instructions

A certification of origin that is the basis for a claim for preferential tariff treatment under the USMCA shall include the below data elements in accordance with the below instructions. UPS provides customers with this information in an effort to help them better understand the USMCA. This information, however, including this USMCA certification of origin form and any other UPS-provided USMCA information, is for informational purposes only. Neither the certification of origin form nor the USMCA information constitutes legal advice. In addition, you, the customer ("you"), agree that it is your responsibility to confirm – and that you have confirmed – that any and all goods for which you claim USMCA preferential treatment and/or that you identify on this USMCA certification of origin form meet all of the applicable USMCA rules of origin for that good(s) (e.g., tariff shift, regional value content, steel and aluminum content, labor value content, etc.) and any other applicable USMCA requirement.

1. Importer, Exporter or Producer Certification of Origin

Indicate whether the certifier is the exporter, producer or importer.

2. Blanket Period

Include the period if the certification covers multiple shipments of identical goods for a specified period of up to 12 months.

3. Certifier

Provide the certifier's name, title, address (including country), telephone number, and email address.

4. Exporter

Provide the exporter's name, address (including country), e-mail address, and telephone number if different from the certifier. This information is not required if the producer is completing the certification of origin and does not know the identity of the exporter. The address of the exporter shall be the place of export of the good in a Party's territory.

5. Producer

Provide the producer's name, address (including country), e-mail address, and telephone number, if different from the certifier or exporter or, if there are multiple producers, state "Various" or provide a list of producers. A person that wishes for this information to remain confidential may state "Available upon request by the importing authorities". The address of a producer shall be the place of production of the good in a Party's territory.

6. Importer

Provide, if known, the importer's name, address, e-mail address, and telephone number.
The address of the importer shall be in a Party's territory.

7. Description and HS Tariff Classification of the Good

(a) Provide a description of the good and the HS tariff classification of the good to the 6-digit level (except, in the case that the relevant rule of origin for the good requires eight digits, identify to the 8-digit level using the HS tariff classification of the USMCA Party into whose territory the good is imported). The description should be sufficient to relate it to the good covered by the certification; and

(b) If the certification of origin covers a single shipment of a good, indicate, if known, the invoice number related to the exportation.

8. Origin Criterion

General Rules of Origin (RoO) Section 202 of the USMCA Implementation Act specifies the rules of origin used to determine whether a good qualifies as an originating good under the Agreement. The HTSUS GN 11 includes both the general and specific rules of origin, definitions, and other related provisions. In general, under the USMCA, a good is originating based on the following four RoO criterion A-D and the good satisfies all other applicable requirements:

- **Criterion A:** The good is wholly obtained or produced entirely in the territory of one or more of the USMCA countries, as defined in Article 4.3 of the Agreement;
- **Criterion B:** The good is produced entirely in the territory of one or more of the USMCA countries using non-originating materials, provided the good satisfies all applicable requirements of product-specific rules of origin;
- **Criterion C:** The good is produced entirely in the territory of one or more of the USMCA countries exclusively from originating materials; or
- **Criterion D:** The good is produced entirely in the territory of one or more of the USMCA 6 countries. It is classified with its materials, or satisfies the "unassembled goods" requirement, and meets a regional value content threshold of not less than 60% if the transaction value method is used, or not less than 50% if the net cost method is used (not including RVC for autos); except for goods in Chapter 61-63 of the HTSUS.

https://www.cbp.gov/sites/default/files/assets/documents/2020-Jun/Updated%20USMCA%20Interim%20Implementing%20Instructions%20-%202020%20Sep%2016.pdf

9. Certification, Authorized Signature and Date

The certification must be signed and dated by the certifier and accompanied by the following statement:

I certify that the goods described in this document qualify as originating and the information contained in this document is true and accurate. I assume responsibility for proving such representations and agree to maintain and present upon request or to make available during a verification visit, documentation necessary to support this certification.

© 2020 United Parcel Service of America, Inc. UPS, the UPS brandmark and the color brown are trademarks of United Parcel Service of America, Inc. All rights reserved

APPENDIX G SAMPLING CHECKLISTS

Table G-1. Personnel Preparation Checklist

(Page 1 of 2)

Personnel Briefing	Yes	No	Comments
1. Did you review sampling team responsibilities and identify individual(s) responsible for corrective actions?			
2. Did you ensure that you have met the appropriate personal safety and protection requirements?			
3. Did you identify sampling locations and receive permission to access them, as appropriate?			
4. Did you contact the appropriate utility companies PRIOR to the start of sampling?  By law, utility companies must be contacted prior to the start of digging/sampling so that any underground utilities (gas lines, water lines, electrical lines, etc.) can be marked. A list of one-call centers for each state may be found at: https://call811.com			
5. If sampling on private property, do you have sample receipts to provide to the property owner for all samples collected and removed from the property?			
6. Have you determined the number and type of samples to be collected?			
7. Did you review sample collection methods?			
8. Have you reviewed sample container requirements?			
9. Did you review decontamination requirements, procedures, and locations?			
10. Did you determine holding times and conditions?			
11. Did you determine Performance Evaluation (PE) and Quality Control (QC) sample requirements?			
12. Have you obtained shipping container temperature blanks, if required?			
13. Did you review sample label requirements?			
14. Did you review Traffic Report/Chain of Custody (TR/COC) Record and custody seal requirements?			
15. Have you obtained the laboratory name, shipping addresses, and telephone number?			
16. Did you review shipping container return instructions?			
17. Have you obtained shipping company information (name, telephone number, account number, and pickup schedule)?			
18. Have you obtained shipping schedules?			
19. Did you review shipment reporting requirements and the appropriate contact names and telephone numbers for reporting?			

Table G-1. (Continued) Personnel Preparation Checklist

(Page 2 of 2)

Personnel Briefing	Yes	No	Comments
20. Have you included any sampler comments regarding sampling issues (e.g., low volumes, matrix, suspected concentrations based on field measurements)?			

Table G-2. General Sample Collection Checklist

(Page 1 of 1)

General Sample Collection	Yes	No	Comments
1. Did you identify and mark the sampling location with buoys, flags, or stakes according to the sampling plans, maps, and grids?			
2. If the sampling location is inaccessible, did you contact the appropriate field or Regional personnel for instructions?			
3. Did you use the correct sampling equipment?			
4. Did you follow the correct decontamination procedures?			
5. Did you follow the correct collection procedures?			
6. Did you use the correct sample containers for each sample collected?			
7. Did you use certified clean containers for all samples? Are certificates kept on record?			
8. Did you use certified clean water for all field, trip, equipment, and rinsate blanks? Are certificates kept on record?			
9. Did you collect the correct volume for each sample?			
10. Did you collect the correct type of sample, including primary samples and QC samples?			
11. Did you properly preserve each sample collected?			
12. Did you correctly document and label each sample with all necessary information?  Under no circumstances should the site name or address appear on any documentation being sent to the laboratory, unless the laboratory is a Regional U.S. Environmental Protection Agency (EPA) laboratory.			
13. If sampling on private property, did you provide a sample receipt to the owner of the property for all samples collected and removed from the property?			

Table G-3. Completing Field Logbook Checklist

(Page 1 of 1)

Completing Field Logbook	Yes	No	Comments
1. Did you use waterproof ink when writing in the field logbook?			
2. Did you document sampling project information such as: • Project name, Project ID, and location • Names of samplers • Geological observations, including maps • Atmospheric conditions • Field measurements • Sampling dates, times, and locations?  Under no circumstances should the site name or address appear on any documentation being sent to the laboratory, unless the laboratory is a Regional EPA laboratory.			
3. Did you record sampling activity information such as: • Sampling dates and times • Sample identifications • Sample matrices • Sample descriptions (e.g., odors and/or colors) • Number of samples collected • Sampling methods/equipment • Description of QC samples?			
4. Did you document any and all deviations from the sampling plan?			
5. Did you document any and all difficulties in sampling and/or any unusual circumstances?			
6. Were all errors corrected by crossing a line through the error, initialing the error, dating the error, and then adding the correct information?			

Table G-4. Completing Handwritten Sample Labels Checklist

(Page 1 of 1)

Completing Handwritten Sample Labels	Yes	No	Comments
1. Did the Regional Sample Control Coordinator (RSCC) provide Contract Laboratory Program (CLP) Sample Numbers and Sample Management Office (SMO) Contract Laboratory Program Support System (CLPSS) Portal-generated CLP Case Numbers?			
2. If additional CLP Sample Numbers were needed, did you contact the appropriate Regional personnel?			
3. Were the CLP Sample Numbers and SMO CLPSS Portal-generated CLP Case Numbers on the labels correct?			
4. Were samples uniquely numbered and designated to only one sample?  Samples collected for total metal and filtered metal analyses must receive separate, unique, CLP Sample Numbers.			
5. Were QC samples numbered accordingly?			
6. Were the specific requirements followed for total and filtered metals analysis, QC and PE samples, and SW-846 Method 5035A?			
7. Were all temperature blanks labeled with “TEMPERATURE BLANK”?			
8. Was a sample label containing the CLP Sample Number, SMO CLPSS Portal-generated CLP Case Number, location, concentration, preservative, and the analysis, attached to each sample bottle or container as the sample was collected?  Under no circumstances should the site name or address appear on any documentation being sent to the laboratory, unless the laboratory is a Regional EPA laboratory.			
9. Was clear tape placed over the sample labels to protect the labels from moisture and to help the labels adhere to the sample bottle?  Use only CLEAR tape over the sample labels and avoid wrinkles in the tape and the sample labels.			
10. Were all errors corrected by drawing a line through the error, initialing and dating the error, and then adding the correct information?			

Table G-5. Completing Handwritten Custody Seals Checklists

(Page 1 of 1)

Completing Custody Seals	Yes	No	Comments:
1. If required for the project, did you sign and date the custody seal?			
2. Did you attach a completed custody seal to the sample bottle, container, or plastic bag, placing the seal over the cap or lid of each sample bottle or container or on the bag opening such that it will be broken if the sample bottle, container, or bag is opened or tampered with?			
3. As appropriate, did you attach the completed custody seal to the sample shipping container or cooler, placing the seal such that it will be broken if the container or cooler is opened or tampered with?			
4. Were all errors corrected by crossing a line through the error, initialing and dating the error, and then adding the correct information?			

Table G-6. Packing Sample Container Checklist

(Page 1 of 1)

Packing Sample Container	Yes	No	Comments
1. Did you follow all State, Federal, Department of Transportation (DOT), and International Air Transportation Association (IATA) regulations governing the packaging of environmental and hazardous samples?  If samples contain methanol preservation (e.g., samples to be analyzed by SW-846 Method 5035A), refer to the packaging instructions in Appendix C.			
2. Were all CLP Sample Numbers, SMO CLPSS Portal-generated CLP Case Numbers, analyses, labels, and custody seals attached to the correct sample containers?			
3. Is Modified Analysis indicated if requested?			
4. Was an inventory conducted of CLP Sample Numbers, SMO CLPSS Portal-generated CLP Case Numbers, analyses, and containers, and verified against the TR/COC Records?			
5. Were the correct number and type of PE and QC samples collected?			
6. Were all sample containers sealed in clear plastic bags with the sample label and tag (if applicable) visible through the packaging?			
7. Was suitable absorbent packing material placed around the sample bottles or containers?			
8. Were the outsides of metal containers labeled properly with the CLP Sample Number, SMO CLPSS Portal-generated CLP Case Number, and the analysis of the sample inside?			

Table G-7. Packing Shipping Container Checklist

(Page 1 of 2)

Packing Shipping Container	Yes	No	Comments
1. Were shipping samples in a clean waterproof metal or hard plastic ice chest, cooler, or container in good condition?			
2. Were all non-applicable labels from previous shipments removed from the container?			
3. Were all inside and outside drain plugs closed and covered with suitable tape (e.g., duct tape)?			
4. Was the inside of the shipping container lined with plastic (e.g., large heavy-duty garbage bag)?			
5. Was the lined shipping container packed with non-combustible absorbent packing material?			
6. Were sample containers placed in the shipping container in an upright position not touching one another?			
7. Was a shipping container temperature blank included in the cooler?			
8. Did the documentation in the cooler only address the samples in that container?			
9. Was the site name absent from all documentation?  Under no circumstances should the site name or address appear on any documentation being sent to the laboratory, unless the laboratory is a Regional EPA laboratory.			
10. Was there sufficient packing material around and in between the sample bottles to avoid breakage during transport?			
11. If required, was double-bagged ice placed on top and around sample bottles to keep the samples cold at ≤ 6°C?  Do not pack loose ice into the cooler.			
12. Was the top of the plastic liner fastened and secured with tape?			
13. Was a completed custody seal placed around the top of the fastened plastic liner (if required by the Region)?			
14. Were all sample documents enclosed within the shipping container (e.g., TR/COC Record, PE instructions, and container return instructions) in a waterproof plastic bag?			
15. Was the plastic bag, containing the documentation, taped to the underside of the lid?			
16. Were shipping container return instructions and airbills taped to the underside of the cooler lid?			
17. Was the return address of the shipping container written with permanent ink on the underside of the lid?			
18. Was tape placed around the outside of the entire container and over the hinges?			
19. Were the completed custody seals placed over the top edge of the container so the container cannot be opened without breaking the seals?			
20. Was the return address label attached to the top left corner of the container lid?			

Table G-7. Packing Shipping Container Checklist

(Page 2 of 2)

Packing Shipping Container	Yes	No	Comments
21. Were instructional labels attached to the top of the container, as necessary (e.g., "This End Up," "Do Not Tamper With," or "Environmental Laboratory Samples")?			
22. Have all U.S. DOT regulations been met for the shipment when shipping hazardous samples?			
23. If shipping samples containing methanol as a preservative (e.g., samples to be analyzed by SW-846 Method 5035A), was a label used to indicate the presence of methanol, the United Nations (UN) identification number for methanol (UN 1230), and Limited Quantity?			

Table G-8. Shipping & Reporting CLP Samples Checklist

(Page 1 of 1)

Shipping CLP Samples	Yes	No	Comments:
1. Did you follow all State, Federal, DOT, and IATA regulations governing the shipment of environmental and hazardous samples?			
2. Was a separate airbill filled out for each container being shipped?			
3. Was the airbill filled out completely, including correct laboratory name, address, and telephone number, identification of recipient as "Sample Custodian," and appropriate delivery option (e.g., overnight or Saturday)?			
4. Was the completed airbill attached to the top of the container with the correct laboratory address?			
5. If more than one container was being shipped to the same laboratory, were they marked as "1 of 2," "2 of 2," etc.?			
6. Were the samples being shipped "overnight" through a qualified commercial carrier?			
7. Did you export the electronic COC XML file from Scribe?			
8. Did you upload the electronic COC XML file using the Submit Chain of Custody task in the SMO CLPSS Portal?			
Reporting CLP Samples	**Yes**	**No**	**Comments:**
1. Did you contact the RSCC (or designee) and the Contract Laboratory Program Sample Management Office (SMO) on the same day samples were shipped?			
2. If the samples were shipped after 5:00 PM Eastern Time (ET), were they reported to the RSCC (or designee) and to SMO by 8:00 AM ET the following business day?			
3. Did you notify the RSCC (or designee) and SMO so that SMO will receive the delivery information (including shipping airbill information) by 3:00 PM ET on Friday for sample shipments that will be delivered to the laboratory on Saturday?			
4. Did you provide the RSCC (or designee) or the SMO CLPSS Portal with: • Your name, phone number, email address, and Region number; • Case Number of the project; • Modified Analysis Number, if requested; • Exact number of samples, matrix(ces), and type of analysis; • Laboratory(ies) to which the samples were shipped; • Carrier name and airbill number; • Date of shipment; • Date of next shipment; and • Any other information pertinent to the shipment?			

APPENDIX H GLOSSARY

Analyte -- The specific compound, mixture, element, or ion an analysis seeks to determine.

Analytical Services Branch (ASB) -- The branch of the Technology Innovation and Field Services Division (TIFSD) of the United States Environmental Protection Agency's (EPA's) Office of Superfund Remediation and Technology Innovation (OSRTI) responsible for the overall management of the Contract Laboratory Program (CLP) under the Office of Land and Emergency Management (OLEM).

Aroclor -- Polychlorinated biphenyls (PCBs) or a class of organic compounds with 1 to 10 chlorine atoms attached to biphenyl and a general chemical formula of $C_{12}H_{10-x}Cl_x$. PCBs, commercially produced as complex mixtures containing multiple isomers at different degrees of chlorination, were marketed in North America under the trade name Aroclor.

Case -- A finite, usually predetermined, number of samples collected over a given time period from a particular site. Case Numbers are assigned by the Sample Management Office (SMO). A Case consists of one or more Sample Delivery Groups (SDGs).

Chlorinated Dibenzo-*p*-Dioxin/Chlorinated Dibenzofuran (CDD/CDF) -- A group of organic compounds of tetra- through octa-chlorinated dibenzo-*p*-dioxins (CDDs) and dibenzofurans (CDFs).

Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) -- First authorized by Congress in December 1980, and amended in 1986, CERCLA provided broad Federal authority to respond directly to the release or possible release of hazardous substances that may endanger human health or the environment. CERCLA also established a Trust Fund to provide for cleanup when no responsible party could be identified; hence, CERCLA is commonly referred to as "Superfund."

Congener -- Individual compound belonging to a group or class of compounds with a similar general structure.

Contract Laboratory Program (CLP) -- Supports the EPA's Superfund effort by providing a range of state-of-the-art chemical analytical services of known and documented quality. This program is directed by the Analytical Services Branch (ASB) of the Technology Innovation and Field Services Division (TIFSD) Office of the Superfund Remediation and Technology Innovation (OSRTI) of the EPA.

Custody Seal -- An adhesive label or tape that is used to seal a sample bottle or container that maintains chain of custody and that will break if the sample bottle or container is opened or tampered with.

Cyanide (Total) -- Cyanide ion and complex cyanides converted to hydrocyanic acid (HCN) by reaction in a reflux system of a mineral acid in the presence of magnesium ion.

Data Quality Objectives (DQO) -- Qualitative and quantitative statements that clarify technical and quality objectives, define the appropriate type of data, and specify tolerable levels of potential decision errors that will be used as the basis for establishing the quality and quantity of data needed to support decisions.

Data Validation -- Data validation is based on Region-defined criteria and limits, professional judgment of the data validator, and (if available) the Quality Assurance Project Plan (QAPP) and Sampling and Analysis Plan (SAP).

Deuterated Monitoring Compound (DMC) -- Compounds added to every Gas Chromatograph/Mass Spectrometer (GC/MS) calibration standard, blank, and sample to evaluate the efficiency of the extraction/purge-and-trap procedures, and the performance of the GC/MS systems. DMCs are isotopically labeled (deuterated) analogs of native target compounds. DMCs are not expected to be naturally detected in the environmental media.

Duplicate -- Quality Control (QC) sample required by the laboratory's contract to check the accuracy and precision of inorganic analyses. It is a second aliquot of the same sample to determine the precision of the method.

Equipment Blank -- A sample used to check field decontamination procedures. See Field Blank.

Field Blank -- Any sample that is submitted from the field and identified as a blank. A field blank is used to check for cross-contamination during sample collection, sample shipment, and in the laboratory. A field blank includes trip blanks, rinsate blanks, bottle blanks, equipment blanks, preservative blanks, decontamination blanks, etc.

Field Duplicate -- A duplicate sample generated in the field, not in the laboratory. Checks reproducibility of laboratory and field procedures and indicates non-homogeneity.

Field QC Sample -- Any QC samples submitted from the field to the laboratory. Examples include, but are not limited to, field blanks, field duplicates, and field spikes.

Field Sample -- Primary sample material collected from the field from which other samples, such as duplicates or split samples are derived. A field sample can be prepared in the field and sent for analysis in one or multiple containers, and is identified by a unique EPA sample number.

Field Sampling Plan (FSP) -- Developed to outline the actual steps and requirements pertaining to a particular sampling event, and explains, in detail, each component of the event to all involved samplers.

Holding Time -- The elapsed time expressed in hours, days, or months from the date of collection of the sample until the date of its analysis.

> **Contractual** -- The maximum length of time that the CLP laboratory can hold samples prior to extraction and/or analysis, as specified in the CLP analytical services Statements of Work (SOWs).
>
> **Technical** -- The maximum length of time that samples may be held from time of collection to time of preparation and/or analysis and still be considered valid.

Laboratory Blank -- See Method Blank.

Laboratory Duplicate -- A sample required by the laboratory's contract to check the precision of inorganic analyses.

Laboratory QC Sample -- An additional volume of an existing sample, as required by the laboratory's contract, used to detect contamination or error in the laboratory's practices.

Matrix -- The predominant material of which a sample to be analyzed is composed. Matrix is not synonymous with phase (liquid or solid).

Matrix Spike (MS) -- QC sample required by the laboratory's contract to check the accuracy of organic and inorganic analyses. It is an aliquot of a sample (water or soil) that is fortified (spiked) with known quantities of a specific analyte and subjected to the entire analytical procedure to indicate the appropriateness of the method for the matrix by measuring recovery. See Matrix Spike Duplicate.

Matrix Spike Duplicate (MSD) -- QC sample required by the laboratory's contract to check the accuracy and precision of organic analyses. It is a second aliquot of the same matrix as the Matrix Spike (MS) that is spiked to determine the precision of the method. See Matrix Spike.

Method Blank -- An analytical control consisting of all reagents, internal standards and surrogate standards (or DMCs for GC/MS organic analysis), that is carried throughout the entire analytical procedure. The method blank is used to define the level of laboratory, background, and reagent contamination, also referred to as laboratory blank when defining the level of laboratory contamination.

Modified Analysis (MA) -- A contractual document with modified Statement of Work (SOW) requirements that append to the SOW. All contract and analytical SOW requirements remain in effect unless explicitly modified.

Performance Evaluation (PE) Sample -- A sample of known composition to the EPA; however, it is unknown to the Contractor and is provided to evaluate Contractor performance.

Pesticides -- Substances intended to repel, kill, or control any species designated a "pest," including weeds, insects, rodents, fungi, bacteria, and other organisms. Under the CLP, only organochlorine pesticides are analyzed (e.g., DDT, Dieldrin, Endrin, etc.).

Polychlorinated Biphenyls (PCBs) -- A group of toxic, persistent chemicals used in electrical transformers and capacitors for insulating purposes, and in gas pipeline systems as a lubricant. The sale and new use of PCBs were banned by law in 1979.

Quality Assurance (QA) -- An integrated system of management activities involving planning, implementation, assessment, reporting, and quality improvement to ensure that a process, item, or service is of the type and quality needed and expected by the customer.

Quality Assurance Project Plan (QAPP) -- Document written to meet requirements outlined in the document *EPA Guidance for Quality Assurance Project Plans* (EPA QA/R-5). Prepared in advance of field activities and used by samplers to develop any subsequent plans such as the Sampling and Analysis Plan (SAP) or the Field Sampling Plan (FSP).

Quality Control (QC) -- The overall system of technical activities that measures the attributes and performance of a process, item, or service against defined standards to verify that they meet the stated requirements established by the customer; operational techniques and activities that are used to fulfill requirements for quality.

Regional Sample Control Coordinator (RSCC) -- In most Regions, coordinates sampling efforts and serves as the central point of contact for sampling questions and problems. Also assists in coordinating the level of Regional sampling activities to correspond with the monthly projected demand for analytical services.

Regional Site Manager -- Coordinates the development of data quality objectives and oversees project-specific remedial or removal contractors, State officials, or private parties conducting site sampling efforts.

Rinsate Blank -- A sample used to check decontamination procedures. Also see Field Blank.

Sample -- A discrete portion of material to be analyzed that is contained in single or multiple containers, and identified by a unique sample number.

Sample Delivery Group (SDG) -- A unit within a sample Case that is used to identify a group of samples for delivery. An SDG is defined by the following, whichever is most frequent:

- Each Case of field samples received; or
- Each 20 field samples (excluding PE samples) within a Case; or
- Each 7 calendar day period (3 calendar day period for 7-day turnaround) during which field samples in a Case are received (said period beginning with the receipt of the first sample in the SDG).

In addition, all samples and/or sample analyses assigned to an SDG must have been scheduled under the same contractual turnaround time. Preliminary Results have no impact on defining the SDG. Sample may be assigned to SDGs by matrix (e.g., all soil samples in one SDG, all water samples in another) at the discretion of the laboratory.

Sample Label -- An identification label attached to a sample bottle or container to identify the sample.

Sample Management Office (SMO) -- A Contractor-operated facility operated under the SMO contract, awarded and administered by the EPA.

Sample Number -- A unique number used to identify and track a sample. This number can be recorded on a sample label or written on the sample bottle or container using indelible ink.

Sampling and Analysis Plan (SAP) -- A document that explains how samples are to be collected and analyzed for a particular sampling event.

Scribe -- A stand-alone Windows-based desktop application that samplers can use to automatically create and generate sample documentation prior to and during sampling events.

Semivolatile Organic Analyte (SVOA) -- A compound amenable to analysis by extraction of the sample using an organic solvent.

Standard Operating Procedure (SOP) -- A written document that details the method for an operation, analysis, or action with thoroughly prescribed techniques and steps, and that is officially approved as the methods for performing certain routine or repetitive tasks.

Statement of Work (SOW) -- A document that specifies how laboratories analyze samples under a particular Contract Laboratory Program (CLP) analytical program.

Superfund -- The program operated under the legislative authority of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) and Superfund Amendments and Reauthorization Act (SARA), that funds and carries out EPA removal and remedial activities at hazardous waste sites. These activities include establishing the National Priorities List (NPL), investigating sites for inclusion on the list, determining their priority, and conducting and/or supervising cleanup and other remedial actions.

Superfund Amendments and Reauthorization Act (SARA) -- The 1986 amendment to the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA).

Traffic Report/Chain of Custody (TR/COC) Record -- A record that is functionally similar to a packing slip that accompanies a shipment of goods. Used as physical evidence of sample custody and functions as a permanent record for each sample collected.

Trip Blank -- A sample used to check for contamination during sample handling and shipment from field to laboratory. Also see Field Blank.

Volatile Organic Analyte (VOA) -- A compound amenable to analysis by the purge-and-trap technique. Used synonymously with the term purgeable compound.

Abstract

The use of repeated pulsed neutron (PN) logging has proved effective in numerous CO_2 storage monitoring portfolios around the world. It is regarded as the go-to technique for interpreting saturation changes at the well-bore and has been routinely used for monitoring saturation changes in hydrocarbon reservoirs since tools appeared in the 1960s. The output from this type of tool that is almost always used for saturation monitoring is the so-called 'Sigma' curve, which can be used to distinguish formation fluids on the basis of how fast thermal neutrons are captured.

Through the AQUISTORE Project in Saskatchewan, Canada, the Petroleum Technology Research Centre (PTRC) is demonstrating time-lapse pulsed neutron logging is an appropriate method to monitor near well CO_2 saturation changes in a highly saline reservoir due to a large Sigma contrast between the saline formation waters and the injected CO_2. PTRC has conducted time-lapsed PN logging at the injection well to observe the saturation in the perforated interval and monitor any above zone migration. In addition, a total of 20 PN logging runs were also undertaken to detect the arrival of CO_2 at the project's observation well, which is located approximately 150 m from the injection well.

Here we present an interpretation of a secondary measurement produced by the tools, which is a measure of the hydrogen index obtained from the total count rates of secondary gamma-rays. We use the Ratio output to determine the suitability of this curve for monitoring CO_2 movement and to see any additional benefits compared to the 'Sigma' curve. We find that the Ratio shows slightly better repeatability than the Sigma curve and could certainly be used in its place to monitor saturation changes. Furthermore, at the Aquistore site the wells were drilled with oil based mud. The Ratio measurement is almost unaffected by the presence of oil, and responds strongly to carbon dioxide thus is more reliable for interpreting saturation.

Keywords: Pulsed Neutron logging; saturation; monitoring; repeatability

Nomenclature

PN	Pulsed Neutron
Sigma	Used to distinguish formation fluids on the basis of how fast thermal neutrons are captured.
Ratio	A measure of the hydrogen index obtained from the ratio of the "near to far" detector capture count rates.
Job	refers to all the PN logs run on a particular day.
Pass	refers to an individual log. For example the May 2016 Job comprises a Main Pass and three Repeat Passes over the interval of interest.

1. Introduction

Tracking the migration of injected CO_2 in the subsurface is important for effective management of CO_2 storage operations and to meet regulatory requirements. Migration can be tracked using both surface geophysical and well based methods. A variety of wireline logging techniques are available for use in wells but methods that exploit interactions between neutrons and the formation are normally the most accurate and simplest to apply. The most commonly used tools are Pulsed Neutron Logs (PNL) that measure a property known as 'Sigma'. This quantifies the rate that thermal neutrons are captured and it is directly related to the thermal neutron capture cross-section. Sigma measurements have been routinely used for monitoring saturation changes in hydrocarbon reservoirs since tools capable of measuring it appeared in the 1960s. The use of Sigma for CO_2 monitoring is a natural and straightforward extension of that.

PN tools also produce a second measurement which is related to the hydrogen index (hydrogen atoms per unit volume) obtained from the total count rates of secondary gamma-rays (as opposed to their decay rate). The output is often called the "Ratio" as it is obtained by taking the Ratio of counts from two different detectors seeing both the near and far regions of the well-bore. It is a calibrated measurement in as much as the tool response to a source of gamma-rays with a known strength is measured prior to running the log. Nevertheless, the Ratio measurement is strongly dependent on the precise environment of the tool and in particular it is strongly dependent on what fluids are within the well. Because of this, it is most suited to application in dedicated monitoring wells cemented and cased such that no CO_2 surrounds the tool down-hole during logging. In these circumstances it may be the better measurement for monitoring fluid saturation. For example, the Sigma measurement relies on high formation water salinities to give an accurate estimate of water saturation (as this gives a strong contrast in the responses to water and CO_2). The minimum salinity needed to apply the measurement depends on porosity and the accuracy demanded of the saturation estimate, but as a general rule formation waters fresher than a seawater composition (35,000 ppm NaCl (w/w)) are unlikely to be suitable candidates. This obviously can be a major drawback to the use of the Sigma curve in aquifers with relatively fresh water. The Ratio measurement on the other hand needs some chloride in the formation water but can certainly give a satisfactory result at fairly low salinities.

1.1. This Case Study

At the site of the Aquistore Project in Saskatchewan, Canada, CO_2 is injected into brine-saturated Cambro-Ordovician Winnipeg and Deadwood Formations overlying Precambrian basement rocks for the purpose of CO_2 storage [1]. Injection began in April, 2015, using a single vertical injection well which is perforated over intervals ranging from 3170 m to 3370 m depth. Time-lapsed PN logging was conducted at the injection well to observe the saturation in the perforated interval and monitor any above zone migration. In addition, a total of 20 PN logging runs were also undertaken to detect the arrival of CO_2 at the project's observation well, which is located approximately 150 m from the injection well. The observation well is cased and cemented over its entire depth, and no intervals in this well have been perforated. Due to relatively high salinity of the formation water (320,000 ppm), the Sigma output was used in the first instance for the saturation interpretation [2]. Statistically-significant changes in the Sigma log response have been observed, attributed to CO_2 arrival, from February, 2016 (at which time 45

kilotonnes of CO_2 had been injected) onwards until the last logs were acquired in December 2016 (after 104 kilotonnes of CO_2 had been injected) [2].

Here we extend the interpretation to also include the Ratio output to determine the suitability of this curve for monitoring CO_2 movement and to see any additional benefits compared to the 'Sigma' curve. One advantage of the large number of runs means that the saturation state can be seen to change in stages which can be related to changes in both Sigma and Ratio measurements, i.e. to determine the level of noise. We find that the Ratio shows slightly better repeatability than the Sigma curve and responds strongly to carbon dioxide. Moreover, the Ratio measurement is almost unaffected by the presence of oil, making it highly suitable for monitoring wells drilled with oil based mud.

2. Pulsed Neutron logging technology

2.1. Tool Description and Physics of the Measurement

A typical, modern pulsed neutron logging tool comprises a neutron source and two gamma-ray detectors situated approximately 1m from it and 15cm apart. These, together with power supplies and the down-hole instrumentation are located in a slim housing with an outside diameter of the order of 50 mm. This is small enough to allow logging of most production and injection wells without the need to pull the tubing. The neutron source generates intense bursts of fast neutrons by exploiting the fusion of deuterium and tritium nuclei. The bursts last about 0.1 ms and generate 50,000 to 100,000 fast neutrons. The fast neutrons are slowed to thermal velocities as a result of collisions with nuclei in the borehole fluid, completion and formation. Once the neutrons have slowed to thermal energies they can be captured by certain nuclei and in the process a secondary gamma-ray with a characteristic energy is produced. Gamma-rays that are produced in the vicinity of the detectors, and that travel towards the tool, may be detected. Many commonly occurring nuclei are capable of capturing thermal neutrons but normally the most significant is Chlorine-35. This is both abundant and has a high thermal neutron capture cross-section –i.e. it has a strong affinity for thermal neutrons. Other nuclei either tend to be abundant but have a low capture cross-section –ie are less likely to capture neutrons; or have a high capture cross-section but low abundance. So for most intents and purposes the tool responds exclusively to chlorine which is invariably present as chloride ion dissolved in the formation water.

In the Sigma measurement the rate that the secondary gamma-activity decays after the neutron burst is measured. The decay-rate is expressed on a PN log as the quantity Sigma, which is proportional to it and has units simply named 'Capture Units (CU)'. Logging tools are typically designed to be accurate in the range 0-75 CU which covers the range of readings that are likely to be found in reservoir rocks. Each detector can produce a separate Sigma measurement with slightly different depths of investigation (the further the detector is from the source the greater the depth of investigation).

As already noted there is a second type of measurement that the tool can produce which is based on the total number of secondary gamma-rays detected by the tool. For a two detector tool it is actually the Ratio of the two count-rates that is used. Using the Ratio helps to avoid some of the variation caused by changes in environmental factors such as hole size, bore-hole fluid and temperature and pressure. Because the Ratio is not based on the decay rate, there is actually no need for a pulsed source it just happens to be what is needed for the Sigma measurement. The total secondary gamma-ray count-rate is ultimately determined by the population of thermal neutrons in the vicinity of the detectors (providing there is a reasonable concentration of thermal neutron absorbing nuclei). The Ratio measurement is therefore more sensitive to how effective the tool's environment is at slowing fast neutrons than its ability to capture slow neutrons. The naturally occurring substance that is most effective at thermalizing fast neutrons is water (due to its high hydrogen index).

In comparison, both the Sigma and the Ratio measurement respond to water but where Sigma is mainly responding to dissolved chloride, the Ratio responds directly to the water molecules. There are advantages and

disadvantages to both measurements but an important virtue of the Ratio is that it does not need a high salinity to give a good contrast between water saturated and gas bearing formations. This is particularly important in Australia where formation waters are often fresh [3]. On the other hand, because Sigma is a transient measurement it is largely immune to changes in the tool's environment so, for example, changing the contents of a borehole from water to gas should have little or no effect on the measurement and two different tools run in the same well should give the same result. This has an unfortunate practical consequence that the Ratio measurement is considered in some sense inferior and not worthy of the same care and attention devoted to the Sigma. In the case of the Aquistore project, there is a dedicated observation well (named OBS here) which is permanently filled with brine so both measurements are equally applicable. But the injection well (INJ) changed from being filled with brine prior to injection, to being filled with CO_2 once injection was underway.

2.2. Interpretation of the measurements

As noted above both outputs from the tool are indirectly related to water volume. The Sigma measurement is the weighted average of the individual components making up the formation. This simple mixing law is another reason why Sigma is a popular way of monitoring water saturation. If the sand being targeted for injection is modelled as a three component mixture (matrix, water and CO2) then the measured Sigma is given by:

$$\sum = \sum_{ma}(1-Ø) + \sum_{w}Ø.Sw + \sum_{g}Ø.(1-Sw) \qquad 1$$

Where Sw is the water saturation, Ø is the total porosity and suffixes ma, w and g correspond to matrix, water and CO_2. Porosity is known from open-hole log analysis so the equation can be re-arranged to find Sw (assuming the Sigma values for the components are known). In the case of the Aquistore wells the formation water is extremely saline (200 k ppm(w/w) chloride) and the Sigma value has been estimated to be 145 CU. The 'text-book' Sigma value for a sandstone matrix is 4-5 CU. The Aquistore sands have porosities on the order of 10% so that prior to injection (Sw = 1.00) the expected formation Sigma is 18-19 CU. Carbon dioxide has a low Sigma value of about 1.5 CU, this reflects its relatively low density and the weak thermal neutron capturing ability of carbon and oxygen. Even displacing 20% of the water with CO_2 will have an easily detectable effect on the Sigma measurement reducing it to approximately 16 CU. Note that for the fresher formation waters expected in Australia the equivalent change is only about 0.5C U (from about 6.5 to 6 CU).

The Ratio measurement is more difficult to interpret mainly because a) there are no chart books to provide the end point component values; and b) the well-bore contributes to the measurement. Nevertheless, a knowledge of the physics of the measurement can be used to predict how the Ratio depends on water saturation. Recall that the measurement is responding to the effectiveness of the formation and well-bore at slowing the fast neutrons. The well-bore does not change so its contribution should be constant, the same is true of the matrix. Carbon Dioxide has almost no slowing power, because it has a hydrogen index of zero and has a low density, so the Ratio changes in response to changes in formation water volume (or equivalently saturation). In this case a relationship between water volume and Ratio was found by cross-plotting porosity, found from the open hole logs, against the baseline pulsed neutron log (run before injection commenced). This provided a linear relationship between water volume (Ø.Sw) and the Ratio.

$$Ø.Sw = A.(R - B) \qquad 2$$

Where A, B are constants obtained by a fitting process. The values of A, B are unique to the well (OBS) and the specific type of tool used (Weatherford PND), if either of these changes a different relationship is required. The alternative approach would be to model the Ratio using a Monte Carlo technique.

3. Aquistore Project

3.1. Geology

The Aquistore Project is located in the Williston Basin, a large intracratonic basin centred on North Dakota and extending westward into Montana and northwards into Saskatchewan. The basin is approximately oval in shape with the long axis orientated roughly NW to SE. It is underlain by Precambrian basement and is filled with a more or less complete sequence of sediments ranging from Cambrian to Carboniferous and Jurassic to Tertiary. The sediments include clastics, carbonates and evaporates [4]. The CO_2 is being injected into sandstones of Ordovician and Cambrian age. The seal is provided by an organic rich, black shale of Ordovician age. At its deepest point, in western North Dakota, the basin is about 5000 m deep but in the Aquistore area basement is encountered at about 3500 m [5].

This study primarily deals with the sandstones which are being used for injection. These are divided between the Cambrian Deadwood Formation and the Ordovician Black Island Formation. The former lies directly on basement and is approximately 150 m thick in the Aquistore area. The latter lies immediately above the Deadwood and is about 45 m thick. The Black Island is itself capped with the 30 m thick Icebox shale which is the primary seal for the storage complex. Open hole logs have been run to the intermediate casing shoe(s) at about 620 m MDRT and this includes all the sediments older than Tertiary. The pulsed neutron logs were not run above 2500 m, however, and most are terminated at about 2900 m. This is still well above the injection sands and includes several intervals of low porosity limestone and dolomite as well as evaporites that are useful for understanding the tool responses.

3.2. Wells

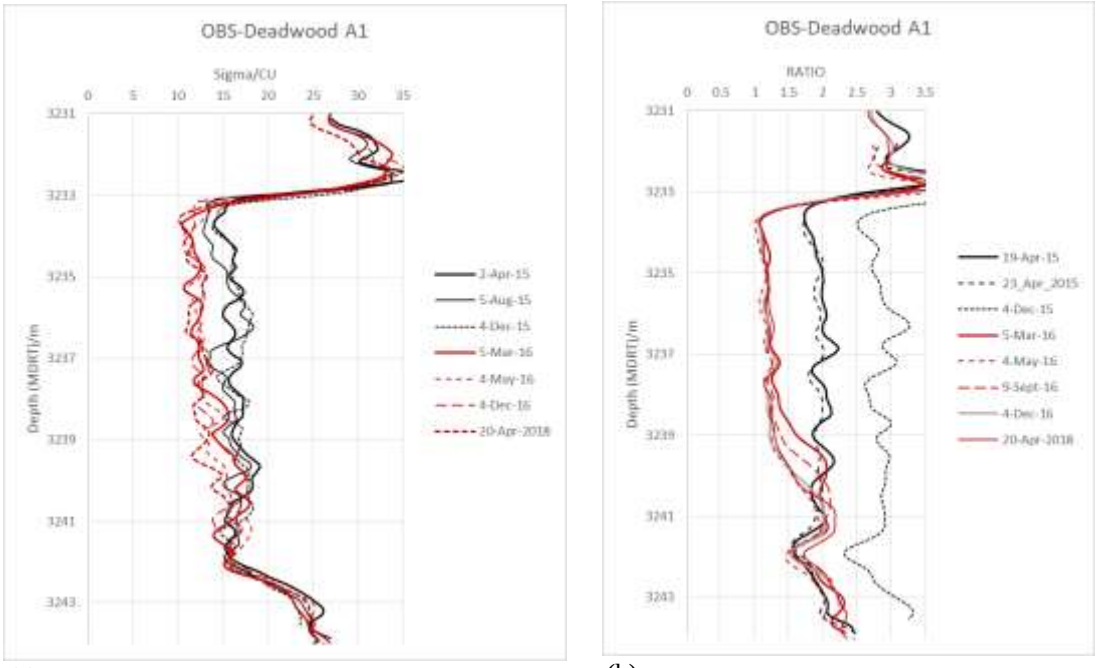
The two Aquistore wells are operated by the Petroleum Technology Research Centre (of Western Canada) and have the full names PTRC-OBS-5-6-2-8 and PTRC-INJ-5-6-2-8. In this paper they will simply be referred to as OBS and INJ. They are both vertical, drilled to a T.D. of approximately 3400 m and are located approximately 150 m apart. The nature of the geology in the area means that they penetrate almost identical sections and the tops and thicknesses of the various units rarely differ by more than a few metres. Although the wells penetrate very similar stratigraphy they have significantly different designs that reflect their different functions. The southerly well INJ is used for injection. It was drilled through the zone of interest with a 251 mm bit (10 ¼") and was subsequently cased with 193mm (7.5" casing) and cemented. Four sets of perforations at depths between 3170 – 3370m expose the permeable sands into which CO_2 is injected. A Packer was set above these and a 114.3 mm tubing string is used for injection. The second well is the observation well and was drilled with a smaller bit of approximately 216 mm. It has been cased and cemented with 114.3 mm casing meaning that there is a relatively thick cement sheath (compared to a typical hydrocarbon well).

3.3. Pulsed Neutron Logging

Pulsed Neutron logs have been acquired in both wells although this paper concentrates on the results from the OBS well, which was acquired with the Weatherford PND tool. Both wells were drilled in 2012 and the open hole logs were acquired then. A baseline pulsed neutron log was run after the wells had been cased. The tool used for that was the Schlumberger RST. The wells were drilled with oil based mud and open hole log analysis showed they were deeply invaded with oil from the mud. This was still present in all the sands in the OBS well when the baseline RST log was run. The net effect of this was that the Sigma values measured in the sands were lower than expected had they been saturated with formation water.

Injection of CO_2 started with some short duration trials early in 2015 and begun in earnest in October 2015. Twelve PND log surveys have been made between April 2015 and April 2018 (seven of these were made after October 2015). A typical survey involved four individual passes over the Deadwood and Black Island sandstones

up to 3150 m (the target for injection). One pass was normally logged up to a depth of at least 2900 m, approximately 250 m above the top of the zone of interest. This allowed the tool response and repeatability to be checked in formations that were well above the influence of the CO_2. Interpretation of the PND logs showed that most CO_2 was being injected into a 10 m thick sand package within the Deadwood Sandstone (between 3232.5 m and 3242.5 mMDRT).



4. Results

4.1. Time-Lapse Results

Sigma and Ratio curves acquired on seven of the surveys are shown in figure 1a and b respectively (several of the earlier surveys have been omitted for clarity). Both measurements show the arrival of the CO_2 plume between December 2015 and March 2016. Sigma falls from approximately 15-16 cu before the arrival of the CO_2 to 10-12 cu after. In the case of the Ratio the equivalent values are 1.8-2.0 and 1-1.2 respectively. A careful examination shows that the base of the sand is still water bearing but that the contact has moved down approximately 2 m between March 2016 and April 2018, this is particularly clear from the Ratio curves.

Agreement between most of the surveys is reasonable until, of course, CO_2 enters the sand. An obvious exception is the Ratio curve acquired in December 2015 which is consistently higher than any of the other surveys and normally exceeds 2.5 in the sand. The curve is in fact offset to higher values for the entire logged interval. The contractor is unable to explain this anomalous response. The Ratio is supposed to be calibrated prior to logging by placing a gamma-ray source of known strength at a fixed position relative to the detectors. Possibly there was an error in this step or possibly the response of the detectors changed at well temperature. Whatever the reason, the log is almost certainly erroneous which is unfortunate as the Sigma curves showed the CO_2 plume passes the OBS well between this survey and the next one.

Both measurements clearly show the arrival of the CO_2 and subsequent downward movement of the contact. The Ratio shows this most clearly partly because the curve is smoother and shows less small scale variation. But in fact the percentage change before and after the arrival of the CO_2 is also greater. The reasons for the differences are discussed below.

(a) (b)

Figure 1: Time-lapse logs over the Deadwood A1 sands in the Observation well (a) Sigma response; (b) Ratio response. Red Curves are post-arrival of the CO_2 plume.

4.2. Repeatability

Some idea of repeatability can be gained by comparing the different surveys before the arrival of the CO_2 plume but it is also possible to compare individual passes made as part of the same survey. The latter is the best way to determine the inherent accuracy of the tool and its detection limits. Figure 2a and b show an example from May 2016. It can be seen that the curves repeat very well. The average Sigma reading and its standard error reading for the four runs is 13.62 (+/-0.02) CU and the equivalent for the Ratio is 1.33 (+/-0.01). These correspond to very small changes in saturation.

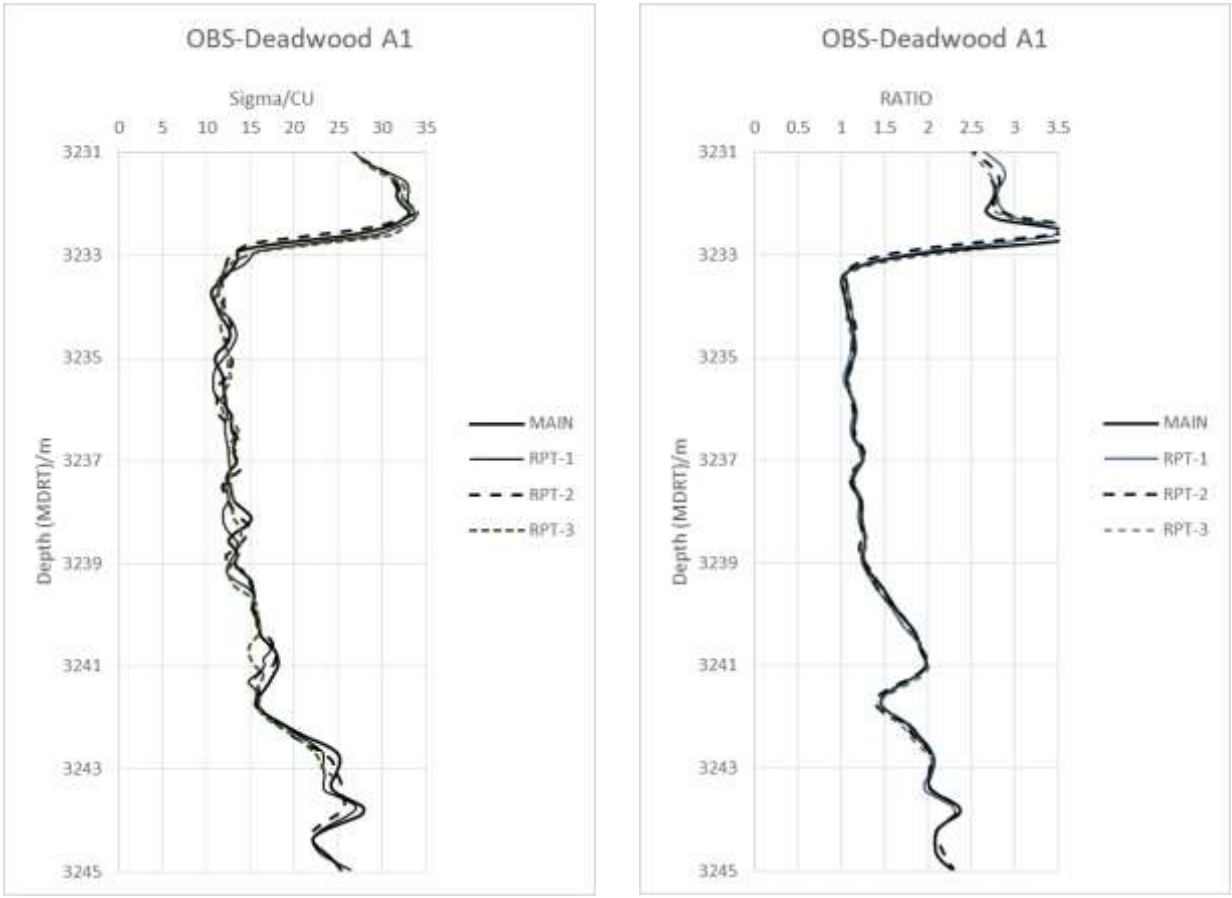


Figure 2: Comparison of repeatability of logging outputs pre-CO_2 arrival (a) Sigma response; (b) Ratio response.

4.3. Oil based mud

As noted earlier the sands were invaded by oil filtrate during drilling and this was still present at the OBS well when the baseline survey was run. In section 2.2 a simple calculation was made that predicted the Sigma reading for the sand saturated with water should be 18 – 19 CU, inspection of figure 2a shows the actual readings varied between 15 – 17 CU. The average Sigma reading for the baseline survey was 15.7 CU whereas the predicted value was 19.1 CU. The reduction is caused by mud filtrate displacing formation water. The Sigma value for the oil is not known but as it contains no chloride (or any other strong thermal neutron absorbers) it will be small. The Schlumberger chart book quotes a value of 22 CU for a 'generic' oil which is far lower than the value for the formation water (estimated at 145CU) [6]. Interestingly for the INJ well the average Sigma reading measured in the baseline survey was very close to the prediction: 17.6 CU predicted vs 17.3 measured. The predicted Sigma at the INJ well is lower because the porosity is lower at that location. In this well water samples were taken using a formation tester and as part of the sampling process the oil had to be pumped out of the formation.

The oil saturation can be found from conventional log analysis and this gave values of 35-40% in the sand considered here. This could be used to predict the Sigma value for the oil invaded sand by substituting into equation

1 but in fact the Sigma curve from the baseline log was used to provide an independent estimate of the oil saturation and this agreed well with the conventional log analysis. The replacement of up to 40% of the water by oil explains the reduced contrast between Sigma logs recorded before and after the arrival of the CO_2. In the case of the Ratio, the effect of replacing formation water with oil is much smaller and potentially non-existent. This is because the hydrogen index of the oil is similar to that of water and therefore a mixture of the two fluids has almost the same ability to thermalize neutrons as water alone. In short, the Ratio measurement is almost insensitive to the presence of oil, and the arrival of the CO_2 produces a much larger change in Ratio than Sigma. As will be discussed below the two measurements together provide strong evidence that the CO_2 has actually removed the oil from the sand.

5. Discussion

Both measurements can be converted to saturation. In the case of Sigma this is achieved by re-arranging equation 1. The accuracy of the saturation depends on the accuracy of the Sigma measurement and properly characterising the Sigma values of the components (the parameters in equation 1). Here the parameters have all been taken from chart-books, but the good agreement between the saturation calculated from open hole log analysis and from the baseline Sigma measurement shows these are reasonable. All of them could be measured in the laboratory if one wanted to remove that element of uncertainty. Figure 3 shows the change in average water saturation (Sw) calculated from Sigma in the sand through time. The presence of the oil in the early surveys can clearly be seen as the Sw is consistently less than 1.

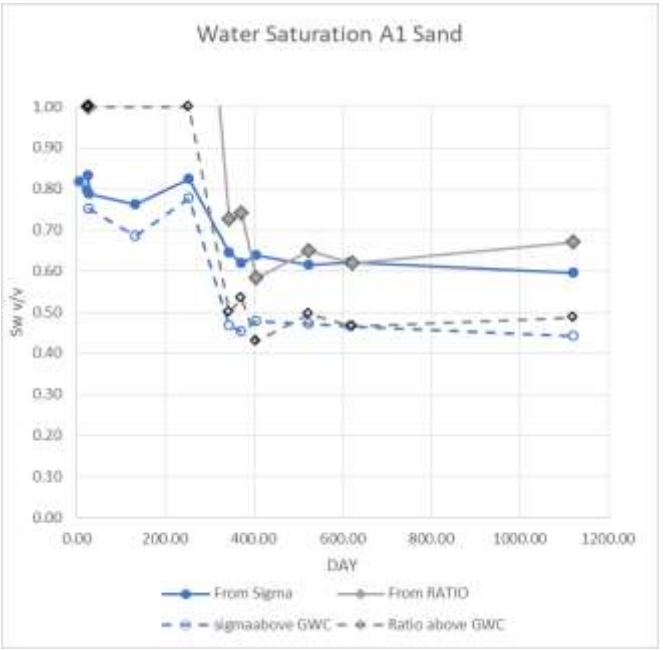

Figure 3: Change in average water saturation (Sw) versus time interpreted from Sigma and Ratio curves (April 2015 is day 0).

Figure 3 also shows the equivalent Sw trend calculated from the Ratio. In this case the calculated Sw for three surveys in April 2015 is 100%. After the arrival of the plume the Sw values fall to similar values to those from the Sigma curve. Unfortunately, the Ratio measured in the survey immediately before the arrival of the plume was the erroneous one discussed above and so has been excluded. The survey before that (August 2015) is also missing because the contractor neglected to provide the Ratio curve. As explained above the Sigma is actually correctly suggesting Sw is less than 100% before the CO_2 arrives, because it is also responding to the oil. The Ratio is almost

insensitive to the oil and so gives the 'expected' Sw of 100%. The good agreement between the Sw values calculated using the two different measurements, after the arrival of the CO_2 actually demonstrates that the oil has largely been removed by the CO_2. This is another aspect of the insensitivity of the Ratio to oil. In effect the Ratio measurement is responding entirely to CO_2 whereas the Sigma responds to CO_2 and oil. If the Sw values agree the oil must have been largely removed. The result is hardly surprising as CO_2 is widely used to mobilize oil in EOR projects but it is interesting to see it in action.

The Sigma curve provides accurate estimates of Sw because of the high salinity and therefore Sigma of the formation water. Analysis of water samples obtained from the INJ well showed it has a chloride ion concentration of 200 kppm (w/w) (this is equivalent to a salinity of 330 kppm although the water contains a high concentration of calcium as well as sodium). This was used to estimate the formation water Sigma value of 145 CU. Even replacing a third of the water with oil still gives a good contrast with the CO_2 bearing formation. For fresher waters the contrast would be less and invasion by oil could seriously compromise the accuracy obtainable. On the other hand, providing there is some chloride ion in the formation water, the Ratio method would still provide good accuracy.

In the previous section it was noted that the Ratio curve has a smoother appearance and amongst other things this makes the contact movement much clearer. The reason for the smoother appearance is due to two factors. Firstly, the measurement combines the outputs from the two detectors and secondly at any point it is based on the sum total of the counts rather than trying to fit a decay to counts accumulated in several short windows. The Sigma measurement is based on the output of one detector –although the two detectors do provide separate measurements which could conceivably be averaged. The disadvantage of the Ratio is that it has inherently lower vertical resolution as it ultimately refers to the whole process from emitting the fast neutrons to detecting the capture gamma-rays. For the Sigma measurement it is the capture process alone that produces the measurement and the source of the neutrons is almost immaterial. Much of the smoother appearance of the Ratio curve is therefore a result of its inherently lower vertical resolution. On the other hand inspection of figure 2a shows that at any depth the Sigma curve can easily vary by 1-2 CU which is simply a reflection of its inherently lower accuracy. As is often the case with logging tools higher vertical resolution comes at a cost of lower accuracy. Accuracy can be improved by making multiple passes and averaging the measurements. By using four passes the signal to noise Ratio can be doubled. An extra pass adds very little additional time to the logging job, particularly if it is limited to the interval of interest.

6. Conclusions

This study confirms that Ratio based measurements provide a valid alternative method to Sigma for monitoring CO_2 plumes. In the case of the Aquistore wells, which are particularly well suited to Sigma monitoring, there is not a great incentive to do this, but where formation water salinities are much lower, Sigma monitoring will at best reveal the passage of the plume and may not even be able to do that. The Ratio measurement on the other hand should be able to quantify CO_2 saturations in even quite fresh water. Thus at deep aquifer sites where formation waters are fresh, e.g. in Australia, the availability of an alternative to Sigma is a major benefit.

Repeated surveys with cased hole Pulsed Neutron Logs in a dedicated observation well have not only allowed the progress of injected CO_2 in this particular facility to be tracked but provide an excellent data set for objectively assessing suitability, accuracy and precision of these tools for use in any geo-sequestration project.

Combining the two measurements brings some additional benefits. In this particular case it was possible to deduce that the CO_2 had succeeded in removing the oil filtrate left over from drilling. In a follow up study we are using the two measurements together to identify and quantify salt precipitation.

Finally, the Ratio measurement should be treated as of equal importance to the Sigma and not simply a by-product. In this particular project the Ratio measurement was clearly in error in a particularly important survey

despite the Sigma measurement being acceptable. Furthermore, for several other surveys it was simply not provided in the initial deliverables.

Acknowledgements

The authors gratefully acknowledge the Petroleum Technology Research Centre and the supporting partners of the Aquistore Project for funding and collaboration on this research. We would also like thank Kevin Dodds of ANLEC R&D for his encouragement of this international collaboration.
